FIGURE 21.10. Small cell neuroendocrine carcinoma. This tumor displays cells that are smaller than those of squamous carcinoma. Nuclei are large and atypical with molding of adjacent nuclei. There is a very high mitotic rate.

Malignant mixed müllerian tumors may involve the cervix, although only about 40 cases have been reported (95). Patients have abnormal bleeding or abnormal Pap smears and cervical masses. The carcinomatous component of these tumors may be squamous or adenocarcinoma. The sarcomatous component may be homologous or heterologous. HPV DNA was detected by polymerase chain reaction in all cases of cervical malignant mixed müllerian tumors reported in one study (96).

Other Malignant Tumors

Various sarcomas have been reported in the uterine cervix, although they are uncommon. A recent review of 1,583 cervical malignant tumors revealed 8 cervical sarcomas (97). Five were carcinosarcomas, and the remainder were unclassified sarcomas, leiomyosarcomas, or endometrial stromal sarcomas. Primary extranodal lymphomas (98) of the uterine cervix are usually diffuse B-cell neoplasms. Primitive neuroectodermal tumors (99) and desmoplastic small round cell tumors (100) have also been described.

Secondary tumors of the cervix include those invading from contiguous organs and metastases from other sites. The former include tumors arising in the uterine corpus, urinary bladder, or rectum. Metastases can originate from many sites, including the ovary, uterus, and more distant primary tumors.

PROGNOSTIC FACTORS

Tumor Size, Volume, Margin Status

In a classic GOG study, Delgado et al. (101) described 3-year disease-free survival (DFS) rates of 94.8%, 88.1%, and 67.6%, respectively, for occult, ≥ 3 cm, and >3 cm stage I squamous cell carcinomas of the cervix treated by radical operation. Survival strongly correlated with depth of tumor invasion of the stroma: 86% to 94% for less than 10 mm, 71% to 75% for 11 to 20 mm, and 60% for 21 mm or greater. In patients without parametrial involvement, the survival rate was 84.9%, but it was 69.6% for those with parametrial tumor extension. These findings have been validated by others, including in FIGO stage II patients, utilizing a 4 cm cut point (102). Rutledge et al. compared patients with FIGO stage IB1 cancers with IB2 cancers treated with RH, finding that LVSI and depth of cervical stromal invasion were more significantly associated with poor prognosis in a multivariate analysis (103). In all these series, there was frequent use of postoperative RT with or without chemotherapy. The use of adjuvant treatment was preferentially given in higher risk patients, narrowing the differences in outcomes and affecting the analysis. In patients treated with curative intent RT, Perez et al. analyzed 1,499 patients treated curatively with RT, finding 10-year actuarial pelvic failure rates of 5%, 15%, and 35% for tumors <2 cm, 2 to 5 cm, and >5 cm, respectively, with the stage IB group. In stage IIB patients, medial parametrial involvement was significantly favorable compared to lateral parametrial extension, and in stage IIIB disease unilateral sidewall extension was significantly favorable to bilateral extension (104). Similarly, Eifel et al. (105) noted a strong correlation between central and pelvic tumor control, disease-specific survival, and tumor size. Pelvic tumor control was 97% with tumors less than 5 cm, and 84% with tumors 5 to 7.9 cm.

Chung et al. used FDG-PET/CT imaging to determine the “metabolic tumor volume” (MTV). In this study, MTV correlated with incidence of lymph node metastasis, parametrial involvement, FIGO stage, and maximum Standardized Uptake Value (SUV). On univariate analysis, DFS was statistically associated with MTV, LN metastasis, parametrial involvement, and LVSI.

On multivariate analysis, age and MTV were found to be independently prognostic for DFS (106).

In patients with stage IB cervical cancer treated surgically, with or without RT, positive margin status conveyed a hazard ratio of 3.92 compared to negative margins. Also, margin status (distance in millimeters in patients with close margins) was significantly associated with an increased recurrence rate. In this series, postoperative RT eliminated local recurrences in patients with close margins and halved the recurrence rate in patients with positive margins (107). Kodama et al. reviewed 84 patients with stage IB-IIB cervical cancer who underwent RH, were found to have positive parametrial margins, and received adjuvant treatment. On multivariate analysis, the presence of vaginal invasion, LN metastasis, and nonsquamous histology negatively impacted DFS. The 5-year OS rate was approximately 90% for patients without any of these factors. The status of the surgical margin did not impact survival in this study (108).

Stage

The FIGO stage is universally accepted for its prognostic significance. For example, Fyles et al. (109), in 965 patients with invasive carcinoma of the cervix, identified FIGO stage as the most significant prognostic factor. Stehman et al., reporting for the GOG on 626 patients treated in phase 3 trials (110), confirmed the prognostic significance of tumor burden, whether measured by FIGO stage, centimeter size, or bilateral disease. Paraaortic node metastases conferred a much greater risk than any of the measures of volume of tumor, however. This emphasizes the fact that FIGO staging does not take into account important prognostic information such as nodal status. Furthermore, stage is only indirectly related to tumor volume, since there can be significant variability in this important prognostic factor within a given stage, resulting in substantial overlap within stage groupings.

Nodal Status

Lymph node involvement is, in most studies, the most significant negative prognostic factor. Reports emphasize higher 5-year survival rates (90% or higher) among surgically treated patients with no evidence of metastasis in the regional nodes, compared to patients with positive pelvic (50% to 60%) or paraaortic nodes (20% to 45%). Delgado et al. (101) reported a 3-year DFS of 85.6% for 545 patients with negative pelvic lymph nodes, compared with 74.4% for patients with one or more positive nodes. In an extensive review of the literature, Creasman and Kohler found that lymph node involvement was reported as an independent risk factor for survival in 88% of series reporting multivariate analyses, versus tumor size/DOI in 61% of series (111). Decreasing 5-year survival rates have been associated with increasing numbers of positive pelvic nodes. As noted above, LN metastasis was shown to be a significantly negative independent prognostic factor in patients with stage IB-IIB disease who underwent initial surgical treatment followed by adjuvant therapy in the setting of parametrial infiltration. (108).

Even micrometastases appear to negatively impact prognosis. Marchiole et al. reported that recurrence was tenfold more likely in an early-stage population of patients treated with radical surgery compared to those without micrometastases (112). Similarly, in a retrospective study from Stanford, a much higher rate of recurrence was seen in early-stage surgically treated patients in whom lymph node micrometastases were detected immunochemically (113).

Lymphovascular Space Invasion

LVSI proved to be a significant prognostic factor in a surgical-pathologic study of 542 patients completed by the GOG (101).

DFS rates were 77% and 89%, respectively, in patients with and without LVSI. Furthermore, LVSI was shown to correlate strongly with pelvic adenopathy. In a case-control study, Marchiole et al. established a relative risk of recurrence of 2.64 in patients with LVSI compared to those without (112). Chernofsky et al. quantitated the amount of LVSI in 101 consecutive patients who underwent surgery for stages IA2-IIA cervical cancer, showing that amount of LVSI was an independent prognostic factor for time to recurrence (114). Milam et al. showed a very strong correlation between LVSI on preoperative biopsy specimen and nodal metastases in surgically treated early-stage cervical cancer (115).

Hypoxia and Anemia

In patients with cervical cancer, it is well accepted that significant anemia at presentation correlates with inferior response rates to RT and with inferior outcomes compared to those without anemia. For example, Ferrandina et al. reviewed 114 patients with locally advanced disease who received preoperative chemotherapy and RT prior to radical surgery. With a value of 10 g/dL as the cut point, the rate of treatment response, measured as pathologic complete response plus only microscopic residual, was significantly higher in patients without anemia at the time of diagnosis (116). A recent review by De Los Santos and Thomas further supports the relationship between anemia and poorer prognosis and decreased responsiveness to therapeutic radiation (117).

Fyles et al. published a review of the basic, translational, and clinical data regarding anemia and its potential impact on radiosensitivity and radiocurability (118). Clearly, the interactions are quite complex. For example, in the presence of anemia, adaptive mechanisms come into play that shift the oxyhemoglobin dissociation curve to the right, providing a compensatory increase in oxygen released into the tissues. There is also an increase in tissue perfusion and oxygenation as hemoglobin decreases due to reduced blood viscosity. However, these effects are potentially less effective in patients with diabetes, smokers, or patients who are vasoconstricting in the presence of marginal cardiac output.

Furthermore, the work of Fyles et al. shows that the relationship between pretreatment hemoglobin levels and direct measurements of oxygen tension in cervical cancers is tenuous. Interestingly, there was a positive correlation between hemoglobin and tumor oxygenation in nonsmokers, but the correlation was negative in smokers. Fyles et al. suggested that the negative prognostic impact of tumor hypoxia might be present only in subgroups of patients. Specifically, they observed worse outcomes with tumor hypoxia only in node-negative patients, manifested by an increase in distant metastases rather than poorer pelvic tumor control (119).

Fuso et al. looked at the impact of pretreatment serum hemoglobin as a predictive factor of response to neoadjuvant chemotherapy (NACT) in patients with locally advanced cervical cancer, finding hemoglobin level to be the most powerful predictor of response. A threshold of 12 mg/dL served to discriminate between optimal and nonoptimal response. However, the authors recognized that a lower hemoglobin level could also be simply a marker for more aggressive disease as opposed to a physiologic variable that could be manipulated for therapeutic benefit (120). The Southwest Oncology Group conducted a phase 2 study in 53 patients to determine whether erythropoietin along with oral iron therapy could safely correct anemia during chemoradiotherapy for cervical cancer. This study did show such an effect, at the cost of a higher-than-expected incidence of deep vein thrombosis (121).

The important question therapeutically is whether correction of the anemia will improve oxygenation status and treatment outcomes. Data from Fyles et al. along with other investigators shows an inconsistent and limited ability for transfusion to impact tumor oxygenation (118). Furthermore, the significant association between tumor hypoxia and tumor size suggests that improving oxygen delivery is unlikely to improve outcomes

owing to factors unrelated to oxygenation, such as number of clonogens, suboptimal brachytherapy dose distributions, and greater risk of metastatic disease.

In spite of the lack of a clear relationship between serum hemoglobin and tumor oxygenation status, various efforts have been directed to the correction of anemia as a therapeutic target. A common approach in cervical cancer and other malignancies has been the use of poietic proteins such as erythropoietin. The GOG initiated a trial to compare maintenance of hemoglobin about 12 g/dL with erythropoietin to “standard” transfusion to maintain hemoglobin above 10 g/dL. Eligible patients had cervical cancer and presented with hemoglobin below 14 g/dL. This study was closed with less than 25% of planned accrual due to a higher observed rate of thromboembolic events in the erythropoietin arm (122). De Los Santos and Thomas reviewed data regarding the incremental increase in thromboembolism with the administration of hemopoietic factors (117). Santin et al. investigated the effect of blood transfusion on immune function in patients receiving radiotherapy for cervical cancer. These investigators measured significant changes in percentages of lymphocyte populations that differed in transfused and nontransfused populations. Furthermore, interleukin-10, a potential dysregulator of lymphocyte function, was only observed in transfused patients. These findings provide a basis for implicating blood transfusion as a possible factor in diminished immune function (123). Additional basic and clinical research will be helpful in determining the reliability of these findings and the potential utility of altered hemoglobin and tumor oxygenation status on tumor sensitivity and treatment outcomes.

Another approach that has been used to potentially address tumor hypoxia is the application of hypoxic cytotoxins. Tirapazamine is one such agent that has shown promise. The GOG opened, but failed to complete, a study comparing RT plus weekly cisplatin to the same regimen plus tirapazamine. However, results from analysis of the 387 evaluable patients accrued showed no improvement in PFS or OS, although there were inadequate numbers of events to draw definitive conclusions (124).

Biomarkers and Bioimaging

Biomarkers and bioimaging have been used to assess prognosis in cervical cancer though clinicopathologic factors still remain the most important factors for prognosis. The earliest biomarkers to be evaluated have been the serum tumor markers. SCCA, cytokeratin fragment 19 (CYFRA 21.1), and cancer antigen 125 (CA-125) (26). While elevated levels of these tumor markers have been correlated with tumor stage, tumor size, cervical stromal invasion, LVSI, parametrial involvement, and lymph node status as mentioned previously, their prognostic value has been debated. In this review, the serial measurements of the most commonly investigated tumor marker, SCCA, were felt to reflect response to treatment and the clinical outcome. In a retrospective study of 550 women with cervical cancer, both pretreatment SCCA and CEA levels were found to be associated with clinical outcome (27).

Cellular biomarkers involved in apoptosis, angiogenesis, or invasive or metastatic potential have also been investigated as prognostic determinants in this disease. A systematic review of the prognostic and predictive significance of these biomarkers in women with cervical cancer was recently published (28). This review included only studies describing a relationship between the biomarker and survival in ≥ 50 women with cervical cancer treated with radiation alone or chemoradiation (28). Of the 1998 studies identified, only 42 studies with 82 biomarkers were included in the analyses. In a univariate analysis, 34 of the biomarkers showed a relation with survival, and 27 were independently associated with survival. The most interesting prognostic biomarkers consisted of SCCA, cyclooxygenase-2 (COX-2), and

markers involved in angiogenesis, hypoxia, and the HER family (EGFR and HER2). In addition, EGFR and HER2 were also associated with a poor response to treatment (28).

Bioimaging with PET and MRI has been explored to evaluate prognosis. There is a significant correlation between cervical tumor uptake of [^{18}F] fluorodeoxyglucose (FDG) measured as the function of a standardized uptake value (SUV_{max}) by PET and treatment response, DFS, and OS (48,125). In addition, a large prospective study with 560 women with clinical Stage IA1-IVB disease evaluated the role of pretreatment [^{18}F] fluorodeoxyglucose PET imaging for lymph node staging and found that disease-specific survival correlated with PET-positive lymph nodes (42). In addition, the pretreatment SUV_{max} of paraaortic lymph nodes by PET has been associated with survival (126). Further work by Grigsby and colleagues demonstrated that posttreatment PET (or PET/CT) scans performed on average 3 months after chemoradiation for locally advanced disease, correlated strongly with response to treatment and disease-specific survival both retrospectively and prospectively (127,128). These studies demonstrate that both pretreatment lymph node status and posttreatment FDG uptake as measured by SUV_{max} correlate with prognosis. While SUV_{max} serves as a functional marker of response, MTV, defined as the volume of tumor tissues with increased FDG uptake, has also been investigated. Chung and colleagues demonstrated that MTV correlated with incidence of lymph node metastasis, parametrial involvement, FIGO stage, and SUV_{max} in a small retrospective cohort of 63 women with Stage IB-IIA prior to surgery. On univariate analysis, MTV was statistically associated with DFS, LN metastasis, parametrial involvement, and LVSI, and SUV_{max} . On multivariate analysis, age and MTV were found to be independently prognostic for DFS (106).

Dynamic contrast-enhanced (DCE-MRI), diffusion-weighted (DWI-MRI), or MRI may be a useful biomarker for response to therapy, recurrence, and OS (35). Mayr and colleagues measured 3-D tumor volume with serial MRI examinations before, during, and after treatment, then defined and validated 4-dimensional volumetric tumor regression parameters, and assessed the correlation with local control, disease-specific, and OS in 115 women with locally advanced cervical cancer (47). Residual tumor volume, slope (representing velocity of tumor shrinkage and clearance during treatment), and area under the regression curve correlated with local control and survival. In addition, these investigators demonstrated that DCE-MRI and MRI parameters quantifying heterogeneous perfusion patterns and residual tumor volumes within 2 to 2.5 weeks into chemoradiation predicted tumor recurrence and survival in 62 women with cervical cancer (46). Others demonstrated a correlation between DCE-MRI and response to therapy (129–131) and locoregional control after treatment (132). Diffusion-weighted MRI correlated to response to treatment in several studies; further investigation will need to be performed to verify that this response to treatment translates into locoregional control and DFS (133–136). Fat saturation sequences with T2-weighting, which enhance the definition of tumor and reduce artifact on MRI, were performed on 23 patients undergoing chemoradiation prior to treatment and during week 4. Changes in T2 fat-saturation tumor intensity during chemoradiation correlated with disease-free but not OS in these patients (137).

At this time, available biomarkers and bioimaging do not replace the standard clinicopathologic prognostic factors for selection of initial treatment. However, given the variability of patient outcomes with standard treatment within several of these clinicopathologic categories, it is very possible that this will change in the near future given the rapid advances in molecular biology and bioimaging. As importantly, the use of biomarkers and bioimaging to predict early response to therapy and patient outcome should provide the opportunity to alter treatment and improve survival in women with this disease.

Histopathology

There have been many reports of similar and dissimilar survival rates for comparable stages of adenocarcinoma and squamous cell carcinoma (108,138–140). Kasamatsu et al. compared squamous and adenocarcinomas managed with initial surgery, finding no difference in prognosis after controlling for other prognostic factors (138). Katanyoo et al. published a large single institution study comparing outcomes of primary RT for locally advanced (IIB–IVA) squamous and adenocarcinomas, again noting no survival differences after controlling for known prognostic factors (139). The largest comparison in terms of patient numbers is found in the retrospective study of Galic et al. who identified nearly 2,500 cases of cervical cancer from the Surveillance, Epidemiology, and End Results (SEER) database. There were nearly 19,000 cases of squamous carcinoma and over 4,100 cases of adenocarcinoma. This study found that, stage for stage, patients with adenocarcinoma fared worse than those with squamous cancer (140). The authors acknowledged the multiple limitations of data within the SEER database.

Three randomized clinical trials of cervical cancer have included subset analyses comparing squamous carcinomas to adenocarcinomas (141–144). These studies, although not definitive, suggest possible differences in outcomes based on treatment delivered. Since the adenocarcinoma subtype is relatively rare, it is unlikely that randomized phase 3 trials could be performed with sufficient power to answer the therapeutic questions raised by these subset analyses (82).

A study of 505 patients with non-squamous cell carcinoma of the cervix examined histologic features for prognostic significance (145). In comparison with tumor limited to the cervix, tumor extension to the uterine corpus was correlated with twice the risk of dying of tumor. The grade and specific type of adenocarcinoma were not of prognostic significance in this study, although well-differentiated villoglandular adenocarcinoma and minimal deviation adenocarcinoma were not evaluated. There is no prognostic significance in the distinction between mucinous and endometrioid adenocarcinoma of the cervix. There is evidence that adenosquamous carcinoma is either a histologically more aggressive tumor than cervical adenocarcinoma or it is diagnosed later in the disease course (89).

Higher tumor grade and vascular invasion are statistically more common in adenosquamous carcinoma than adenocarcinoma of the cervix. The presence of small cell neuroendocrine carcinoma in any amount, even when associated with other types of neoplasm, is an independent prognostic factor associated with aggressive tumor behavior.

GENERAL MANAGEMENT AND RESULTS OF TREATMENT

Severe Dysplasia and Carcinoma *In Situ*

Patients with severe dysplasia/CIN and carcinoma *in situ* (CIS) have essentially no risk of lymphatic involvement and are often treated with local therapies such as conization, laser ablation, cryotherapy, or a simple hysterectomy. These various techniques have comparable efficacy. The more conservative approaches are preferentially used when a patient wishes to have more children. Patients with HIV infection, high HPV viral load, positive margins, older age, and residual high-risk infection following conservative management have a higher recurrence rate (146,147). Detection of residual high-risk HPV infection following conservative management predicts for a higher recurrence rate after conservative treatment (146,147). In a classic study, Kolstad reported results of conization in treatment of CIS.

Therapeutic conization was performed in 795 patients; 2.3% had recurrent CIS, and 0.9% developed invasive cancer (148). Two hundred and thirty-eight patients were treated with hysterectomy and the corresponding rates were 1.2% and 2.1%, respectively. Luesley et al. reported a 91% success in over 600 patients treated with LEEP (149). Martin-Hirsch et al. in a review of the Cochrane Gynecologic Cancer Group registry, evaluated 23 trials in treatment of CIN. They concluded that there was no clearly superior surgical technique for treating CIN (150).

Instances in which conization might be preferred to ablative procedures such as laser or cryotherapy include presence of a positive ECC, treatment of AIS, and inadequate colposcopy due to the advantage of having a pathologic specimen. All uterus-sparing procedures have potential adverse effects including cervical stenosis, predisposition to preterm labor in subsequent pregnancies, persistent vaginal discharge, and possible infertility.

Temkin et al. reviewed 146 patients who had undergone cold knife conization after having been treated with LEEP for CIS (151). Of 146 patients, 133 had residual CIN on cone biopsy, and 15.8% had invasive carcinoma. Patients with residual CIN 3, ectocervical and endocervical margins with CIN, and positive endocervical curettings after conization were more likely to harbor or develop invasive disease. Lu et al. evaluated 449 patients with CIN 3 treated with conization (152). They found that a positive postcone ECC was the most significant factor predicting persistent disease (65.5%), versus 7.6% with a negative postconization ECC. Positive endocervical margins and multiquadrant disease had an odds ratio of 2.97 for persistent disease. The only preoperative indicator of persistent disease was age greater than 50. Given these data, patients with positive ECC after conization or positive endocervical margins on a cone specimen for CIS should have repeat conization prior to hysterectomy to avoid inappropriate treatment for invasive disease.

Of interest is data reported by Case et al. evaluating CIN in adolescent women in which 192 patients with CIN 2,3 underwent conization. On follow-up, 55% had abnormal cytology but no invasive cancer was found (153). This may reflect a high infection rate and point prevalence with HPV in adolescents rather than true recurrence. The new screening guidelines suggest beginning at age 21, taking into account the transient nature of HPV infection in that population. This approach attempts to avoid unnecessary overtreatment in adolescents and young women and its possible consequences such as impaired fertility and adverse pregnancy outcomes.

Since patients with CIS have virtually no risk of pelvic adenopathy, it is also appropriate to treat with only intracavitary RT if the patient is deemed a poor surgical candidate. Tumor control rates of 100% have been reported. Grigsby and Perez successfully treated 21 such patients with intracavitary RT, finding excellent outcomes with no adverse treatment sequelae (154).

Stage IA

The concept of “microinvasion” (equating to FIGO stage IA) should define tumors that penetrate the basement membrane but have little or no risk of nodal involvement or dissemination. Controversies remain in regard to the clinically relevant definition of microinvasive squamous carcinoma of the cervix, particularly as conservative treatment options, including fertility sparing, have become more common. Takeshima et al. performed a clinico-pathologic analysis of 402 patients with invasive squamous carcinoma of the cervix whose tumors demonstrated no more than 5 mm of stromal invasion (155). Although the incidence of nodal metastasis was only 1% among 82 patients with invasion limited to 3 mm, it was nearly 7% in 73 patients with 3 to 5 mm of invasion. Nevertheless, recurrences were rare and were nearly exclusively limited to tumors with more than 7 mm of horizontal spread. In an accompanying editorial, Creasman

noted that this work validated the FIGO definition of microinvasion and potentially opens up the IA2 patients for consideration of more conservative surgical approaches (156).

Hou et al. conducted an extensive review of the literature regarding IA1 and IA2 microinvasive adenocarcinoma, defining a “high-risk” group to include LN involvement or LVSI, positive surgical margins, or recurrence. These “high-risk” patients were compared to a database of patients with MID by the SEER project. Although survivals approached 99% in both IA1 and IA2 subgroups, the IA2 patients were much more likely to have had more radical surgery and adjuvant treatment. Tumors of endometrioid histology were much more likely to be in the high risk group, and these tumors were associated with late recurrences and worse survival, irrespective of substage (157).

Stage IA1 carcinoma is usually treated with conization or hysterectomy, and the control rate approaches 100%. Absence of LVSI plays a key role in opting for conservative management of patients with MID, as its presence may herald a higher incidence of lymphatic involvement. Therefore, pelvic LND is only indicated if LVSI is present. If fertility is not a consideration and prognostic factors for recurrence such as positive postcone ECC or involved margins are present, a hysterectomy is the standard option for definitive treatment of stage IA1.

Management of stage IA2 disease is more controversial. Historically, patients with FIGO IA2 disease with LVSI are not candidates for conservative surgical approaches in most circumstances since the risk of pelvic lymphatic metastasis is 5% to 13%. It is probably the case that most clinicians recommend a modified (Type II) RH and PL for stage IA2 disease, although curative intent RT is an equivalent option. However, the role of RH and the need for parametrial resection have been challenged in this population. In the Covens et al. evaluation of 842 patients, 6% had positive pelvic nodes and 4% had parametrial involvement. Parametrial invasion was associated with LVSI, tumor size greater than 2 cm, higher tumor grade, greater depth of invasion (DOI), and pelvic node metastasis. The incidence of parametrial involvement in patients with tumors less than 2 cm, negative pelvic nodes, and DOI of less than 10 mm was 0.6%. They concluded that because most patients with positive nodes and deep invasion will likely receive adjuvant pelvic RT, resection of the parametrium may not be necessary (158). Similar data has been reported from other groups (159,160). In addition to these reported high control and cure rates, Bisseling et al. described a high level of successful pregnancies following conservative treatment (160).

In patients who are medically inoperable, intracavitary RT may be used successfully. Hamberger et al. studied 151 patients with stage I treated with intracavitary radium. None of the patients with stage IA recurred (161). Grigsby et al. treated 34 patients with stage IA with 13 receiving intracavitary RT only and the remaining 21 treated with pelvic RT. Only 1 patient with stage IA recurred. The overall complication rate was about 6% (154).

Adenocarcinoma—Early Disease

The incidence of cervical adenocarcinoma has increased in the past 40 years. AIS presents a potential diagnostic and therapeutic challenge. The term “microinvasion” is controversial in describing glandular lesions as accurate measurement of DOI in glands may be difficult. Schorge et al. provided some parameters for defining stage IA1 adenocarcinoma (162). Almost all AIS lesions are associated with HPV with 18 being the predominant type.

Management of AIS is controversial. Bull-Phleps et al. evaluated 101 patients with a mean age of 29 treated for AIS with excisional procedures. Cold knife conization had a much higher negative margin rate than LEEP (72% vs. 47%). Pregnancies followed in 49 patients, and 35 delivered at term. There were

2 preterm births and 8 spontaneous miscarriages. Approximately one-third had a repeat cone biopsy, and 5 required a hysterectomy (163). Shin et al. reported on 92 patients with AIS treated with conization with negative margins (164). During a 30-month follow-up, none had recurrent AIS. Sixty-two percent of those with positive margins after conization had residual disease on hysterectomy specimens. Lea et al. highlighted the importance of postconization ECC, demonstrating a positive predictive value of 100% for detecting residual disease (165). Salani et al. reviewed 1,278 patients with AIS of the cervix who underwent conization. Almost 7% required repeat excision. Of 671 patients followed conservatively, the rate of recurrence for those with negative versus positive margins were 2.6% and 19.4%, respectively. The rate of invasive cancer according to margin status was 5.2% in positive margins versus 0.1% in those with uninvolved margins (166).

Given the critical role of margin status postconization, a cold knife cone may be the preferred excisional method compared to LEEP in patients with AIS. The most successful conservative management protocols require negative margins and no LVSI. Therefore, careful counseling and follow-up are warranted. Margin status, postcone ECC, and LVSI are significant predictors of residual disease, recurrence and invasive cancer. The recommended surveillance after conization for AIS includes cytology and ECC every 4 to 6 months.

Stage IB–IIA (Nonbulky)

Stage IB is divided into IB1 (lesions less than 4 cm) and IB2 (lesions confined to cervix >4 cm). IB1 lesions and selected IIA 1 lesions without extensive vaginal involvement can be treated with either RH and pelvic lymph node dissection (PLD) (followed by tailored chemoradiation as indicated by surgical findings) or primary chemoradiation. The preference of one over the other depends on the institution, the oncologists involved, the general condition of the patient, and tumor characteristics. Surgery is the preferred option in younger women as ovarian function and vaginal length, and thus sexual function, can generally be better maintained. Transposition of the ovaries to the abdominal wall or the gutters away from the field of RT may prevent radiation-induced ovarian failure. The preservation of function correlates with the scatter dose to the ovaries. The rate of ovarian failure is low with scattered doses ≤ 300 cGy. Up to a quarter of patients with ovarian transposition will develop symptomatic ovarian cysts requiring operative interventions, which can lower the rate of preservation of retained ovarian function.

RH can be performed through an abdominal, vaginal, or minimally invasive approach (traditional laparoscopy and robotic assisted). As salpingo-oophorectomy is not part of RH, ovarian removal should be based on the patient's age or other factors. The rate of ovarian metastasis is very low. The two most common types of RH used in treatment are classes II and III, described elsewhere in the chapter. Landoni et al. compared these two approaches in a prospective, randomized trial in 238 patients (167). Type II had a significantly decreased mean operative time (135 vs. 180 minutes), and the rate of blood loss and transfusions was comparable. Immediate postoperative complications and length of hospital stay were also similar. The long-term complication rate was significantly less in Type II versus Type III (13% vs. 28%). The use of postoperative RT, recurrence rate, and death rate due to disease were similar in both arms. The OS was 81% and 77%, respectively.

Nam et al. performed a retrospective analysis of outcomes with laparoscopic RH with or without PLD with conventional RH (168). Operating time, complication rate, and number of lymph nodes obtained were similar with the two approaches. Hospital stay was shorter with the laparoscopic technique. Overall, recurrences were lower with the standard operative route, leading the

authors to recommend limiting the laparoscopic approach to patients with tumor diameters less than 2 cm.

Radical operation will shorten the functional length of the vagina, but pliability and transudative lubrication are usually preserved. Jensen et al. documented a substantial negative impact on sexual function that is persistent following RH (169). Radiation therapy can reduce length, caliber, and lubrication of the vagina; however, these symptoms can be alleviated in some patients with hormonal replacement and vaginal dilatation. The evidence to differentiate between surgery and radiation based on sexual function is poor. A strong predictor of posttherapy sexual function is the level of activity prior to therapy. The postmenopausal patient who is not sexually active may have complete obliteration of the vagina, precluding follow-up examination. Combined modalities appear to have a more pronounced effect than either radiation or operation alone.

Fromovitz et al. evaluated 350 patients who underwent RH and pelvic LND. Only 7.7% had parametrial involvement. Factors associated with parametrial spread were size greater than 2 cm, LVSI, high grade, and nodal involvement. Of patients with tumors less than 2 cm and no LVSI, there was no parametrial involvement. These data are provocative in that patients with small tumors with negative LVSI may be candidates for less radical surgery such as simple hysterectomy, simple trachelectomy, or conization (170).

In terms of outcome, radical surgery and definitive chemoradiation have similar good outcomes. Typically, 5-year survival for stage IB patients is 85% to 90% and 65% to 75% for stage IIA. Landoni et al. reported a prospective study of RH versus RT (144). In the RH arm, patients with parametrial involvement, deep stromal invasion, and/or positive nodes received postoperative RT. Fifty-four percent (62 out of 114) and 84% (40 out of 55) of stages IB1 and IB2 received postoperative RT, respectively. Severe morbidity was seen (28%) in the surgical arm (mostly combined surgery and RT) compared to 12% in the RT arm. No difference was seen in disease-related outcomes.

Results of therapy comparing modalities should include all patients evaluated for each therapeutic modality. This applies particularly to surgical series. Findings revealed at operation may change the treatment plan, excluding some high-risk patients. This is exemplified by a report by Delgado et al. (171) for the GOG. Member institutions entered 1,125 patients prior to operation. There were 80 ineligible patients after pathology review. An additional 129 patients were explored, but the hysterectomy was abandoned because of intraoperative complications in 49 patients, or because of extent of disease beyond the uterus in 80. Failure to account for these patients in other series overestimates the efficacy of the operative procedure.

Fertility-Sparing Surgery/Radical Vaginal, minimally invasive and Abdominal Trachelectomy

Almost 30% of women diagnosed with cervical cancer will be younger than 40 and 40% will have early-stage I disease. Preservation of fertility can be a major consideration in treatment if an acceptable oncologic outcome can be obtained. There have been major advances in fertility-sparing surgery (FSS) in women with stage IA2 to IB1 cervical cancer. Dargent pioneered the procedure of transvaginal resection of cervical and paracervical tissue (vaginal radical trachelectomy [VRT]) and proximal vaginal, placement of a permanent cerclage at the cervico-uterine junction, and a laparoscopic pelvic lymphadenectomy (LPL) (172).

Plante et al. reported on 72 patients treated with VRT and LPL (173). Median age was 32, with 74% being nulligravid. Fifty pregnancies occurred in 31 women. Miscarriage rates in the first and second trimester were 16% and 4%, respectively, and 72% of pregnancies reached the third trimester. The overall prematurity rate was 16% to 19% versus 12% in the general population.

In a review, Boss et al. reported that of patients electing FSS, 43% attempt conception, 70% conceive, 49% deliver at term, and 15% have cervical stenosis causing infertility (174).

Marchiole et al. compared VRT with LPL to radical vaginal hysterectomy (RVH) with LPL in patients with lesions less than 2 cm (175). They reported similar intraoperative complication rates (2.5% vs. 5.8%, respectively) and postoperative complication rates of 21.2% and 19.4%, respectively. The recurrence rates were also similar, 5.2% and 8.5%, respectively. Ungar et al., among others, have reported an abdominal approach to radical trachelectomy (ART) (176). Nick et al. reported their experience with robotic-assisted RT versus open and found a lower blood loss and decreased hospital stay. Long-term safety data are still pending (177).

In terms of patient selection, appropriate lesions include FIGO stage IA1 without extensive LVSI and IA2 or IB1 lesions less than 2 cm with limited endocervical involvement. Although early data is encouraging, no level I evidence exists to adequately compare safety and efficacy between conservative and radical surgical approaches. Whether adenocarcinomas are appropriately managed in this fashion is subject to debate; however, in the literature, close to 40% of cases were of glandular histology. Schneider reviewed the literature and found that in patients with tumor size less than 2 cm the recurrence rate was 2% to 5% with an increase in prematurity of 2 to 3 times, compared to women with intact cervix (178).

Bulky IB Carcinoma of the Cervix

Bulky endocervical tumors and the so-called barrel-shaped cervical cancers have a higher incidence of central recurrence, pelvic and paraaortic lymph node metastasis, and distant dissemination. Historically, adjuvant extrafascial hysterectomy following preoperative RT was an accepted treatment approach. The GOG performed a randomized trial in which 256 eligible patients with carcinomas of the cervix ≥ 4 cm were treated with external beam and intracavitary irradiation, or with a slightly lower dose of intracavitary irradiation and the same external beam pelvic irradiation followed by an extrafascial hysterectomy (179). The 3-year DFS and OS rates were 79% and 83%, respectively, and were virtually identical in the irradiation alone and the combined irradiation and surgery groups. The incidence of progression was somewhat higher in the irradiation alone group (46%) compared to the combined therapy group (37%) ($p = 0.07$). However, it appears that surgery does not contribute to increased survival compared to RT alone in patients with “bulky” stage IB disease. A favorable impact on the local recurrence rate with adjuvant hysterectomy is likely, and an improvement in survival for patients with tumors 4 to 6 cm in diameter is suggested. Although retrospective, a similar study done at the University of Virginia compared similar groups of patients with IB2 cervical cancer who received definitive chemo-RT or a preoperative regimen of chemo-RT followed by extrafascial hysterectomy. There was no significant difference in DFSs. Although there was a trend toward more GI toxicity in the definitive chemo-RT group, this did not reach statistical significance. A subset analysis suggested a higher recurrence rate in smokers, especially those receiving definitive chemo-RT (180).

A different retrospective comparison was done at Memorial Sloan Kettering Cancer Center, in which patients with FIGO IB2 cervical cancer treated either with RH with tailored postoperative RT or definitive RT or chemoRT. Medically compromised patients were more likely to be treated without surgery. The 3-year PFS rates were 52% and 55%, respectively, for the RH and definitive RT groups. Over half of the patients managed initially with RH received adjuvant RT. Complications were minimally lower in the definitive RT/chemoRT group (181). Kamelle et al. retrospectively analyzed 86 patients with IB2 tumors treated with RH (182). Over half the patients received

postoperative RT. This study identified presence of LVSI as the only independent predictor of recurrence and argued for the utility of RH up front in the management of patients with intermediate-risk IB2 cervical cancers when there is no evidence of LVSI. Two accompanying editorials questioned several aspects of the analysis, including the diagnostic accuracy of a cervical biopsy in determining LVSI, the small numbers of patients and wide confidence intervals, the possible inferiority of RH compared to modern chemoradiation, and the wisdom of relying on a single variable to determine therapy when there are a number of other recognized considerations for prognosis and treatment selection (183,184).

An alternative approach involving neo-adjuvant chemotherapy prior to RH and tailored postoperative RT was investigated in a GOG randomized trial. Although the trial closed due to slow accrual, 291 patients were enrolled and randomized. When these patients were analyzed, there was no evidence that NACT provided any advantage compared to patients who went directly to RH (185).

Stages IIB, IIIB, and IVA

Patients with stage IIB, IIIB, IVA disease are treated mainly with definitive concurrent chemoradiotherapy (CCRT) in the United States (186). RT alone series have shown 5-year survival rates of 60% to 65% for stage IIB, 40% to 50% for stage IIIB, and 10% to 20% for stage IVA patients (187,188) with complication rates of 4% to 13%. Based on multiple randomized clinical trials (189–191), concurrent cisplatin is a standard agent to combine with RT. Other chemotherapy agents that have been used successfully include 5-fluorouracil (5-FU), mitomycin, carboplatin, paclitaxel, epirubicin, and gemcitabine (192). This data is nicely summarized in an article by Eifel (Table 21.2) Subset analyses of these trials (189,190) and a meta-analysis (193) demonstrated significant improvement in OS in stage IIB patients and marginal significance in stage III/IVA. Based on these findings, the National Comprehensive Cancer Network (NCCN) guidelines suggest CCRT as standard treatment for stage IIB, IIIB, and IVA disease (194). As acute effects are increased when chemotherapy is added to RT, the clinician must always weigh the risk of acute side effects and the threat posed by them with the potential benefit in patients with significant comorbid illnesses and poor performance status.

In Japan as well as in some European and Latin American countries, some stage IIB patients have been treated with radical surgery, sometimes with NACT (NAC), despite lack of sufficient evidence of its efficacy (195–197). NCCN guidelines do not suggest surgery as a treatment of choice for stage IIB patients (194).

External Irradiation Alone

The Radiation Therapy Oncology Group's Patterns of Care Study (PCS) revealed that outcomes in patients treated with external beam radiotherapy (EBRT) alone were significantly lower than those treated with EBRT and intracavitary brachytherapy (ICBT) (198). Consequently, standard definitive radiotherapy for cervical cancer consists of combined EBRT and ICBT. However, patients who cannot receive appropriate ICBT (e.g., presence of vaginal fistula, narrow vaginal anatomy) may need to be treated with EBRT alone. Compared with poor treatment results from old series, encouraging preliminary data have been reported recently. Matsuura et al. reported their experiences of EBRT alone for seven patients with cervical cancer who could not receive ICBT for various reasons (199). They applied 3-dimensional EBRT with field-within-field accelerated hyperfractionation, and showed 2-year pelvic control of 86% with no severe late toxicities. Park et al. reported preliminary data using a 3-dimensional conformal boost with a “real-time tumor tracking radiotherapy system”

Table 21.2 Prospective Randomized Trials of Concurrent Radiotherapy and Chemotherapy for Patients with Locoregionally Advanced Cervical Cancer

for 10 patients with cervical cancer who were unable to receive ICBT (200). They demonstrated a 2-year local failure free survival rate of 54%. A grade 2 rectal complication was seen in one patient. Although some propose that IMRT could be an effective alternative to ICBT, there are some challenging issues concerning interfraction and intrafraction organ motion and changing anatomy due to tumor regression or even progression before and during treatment. At present, IBCT is still part of standard treatment, due to a long track record of success, avoiding the problem of organ motion, and its superior ability to protect normal structures (201).

UNUSUAL CLINICAL SITUATIONS

Node-Positive Early-Stage (Operable) Cervical Carcinoma

Should the Hysterectomy Be Completed?

Pathologic pelvic node metastases are present in 10% to 27% of stage IB and IIA patients (7,202). The incidence is related to various

factors including tumor diameter, depth of stromal invasion, parametrial involvement, and LVSI (202). Even with more advanced imaging techniques, sensitivity for detecting positive nodes preoperatively is still unsatisfactory. The ACRIN-6651/GOG-183 was an intergroup multicenter trial of MRI and CT as potential predictors of lymphatic metastases in women with early invasive cervical carcinoma. This study showed that histologic lymph node involvement was not recognized by imaging in 34% of RH and lymph node dissection (RH-LND) specimens (41). PET is a promising imaging modality for detecting small nodal metastases which are difficult to be detected with CT/MRI. However, some data are still worrisome in this regard (203). As a result, it is not uncommon for the surgeon to find grossly positive nodes intraoperatively. In this situation, the dilemma becomes whether to proceed with the RH or to abandon the surgery and opt for curative intent CCRT.

Whitney and Stehman reviewed the GOG #49 database and found that, in 98 of 1,127 patients with clinical stage IB tumors, the surgeon abandoned the operation. Sixty-eight of these were patients with squamous carcinomas whose surgery was abandoned due to tumor extension beyond the uterus rather than for medical reasons, forming the basis of their report (204). Of these, 17 patients (1.5% of the total group, 25% of the study group) had grossly positive pelvic lymph nodes as the sole manifestation of extrauterine disease. Most patients received curative intent RT when feasible. Patients with positive pelvic nodes did poorly, with 8 of 12 failing, including 3 with distant disease. The median recurrence-free interval was only 10 months, and the median survival was 17 months.

Leath et al. reviewed 23 patients with early-stage cervical cancer who had the RH aborted because of pelvic extension (11 patients) or positive nodes (12 patients). All received RT as definitive treatment. The 5-year OS was 83%, suggesting that the aborted RH did not negatively impact outcome (205). Suprasert et al. compared the outcome of 23 patients in whom the RH was aborted due to the intraoperative finding of grossly positive nodes with that of 35 patients who were diagnosed having positive node, after completion of the surgery. Although the outcome was substantially better in patients who completed surgery, the authors pointed out that surgical group had much better prognostic factors (206).

Richard et al. analyzed data for patients with completed versus abandoned RH identified from the SEER database from 1988 to 1998 (207). From a cohort of 3,116 women with stage IB cervical cancer, 265 (8.7%) had positive pelvic nodes and a complete pelvic and paraaortic lymphadenectomy. Of these, 163 patients completed their RH, while RH was abandoned in 55 patients. All patients included in the analysis received postoperative RT. The investigators found that 5-year survival for the completed RH group was 69% compared with 71% for the RH abandoned group ($p = 0.46$).

Based on available data, it is difficult to conclude that completing the hysterectomy improves the outcome. Possible disadvantages of surgery include delaying the initiation of RT, adding surgical morbidity, and utilizing 2 treatment modalities when 1 (RT) would likely suffice. Furthermore, leaving the uterus in place provides an appropriate conduit for intracavitary RT and probably lessens the risk of complications. Clinicians who believe that completing the RH improves outcome, even with positive nodes, will point to data suggesting that patients who undergo RH, as a group, have a better outcome than the patients in whom the procedure is aborted. Others will point out that the groups are not prognostically similar and suggest that a reasonable approach is to have the surgeon resect or debulk grossly positive nodes and surgically stage the paraaortics but abort the RH. RT with chemotherapy would then become the primary therapy.

Should the Lymphadenopathy Be Debulked?

Data suggests an advantage for surgically resecting grossly positive lymph nodes prior to definitive RT, although some have

questioned the benefit in the vast majority of patients (208). Theoretical bases of the strategy include adequate control of metastatic nodes leading to improve OS and better control of gross metastatic nodes than is achievable with RT alone. Kupets et al. calculated that only 7 out of 300 patients undergoing surgical debulking of positive nodes could benefit in terms of survival. These calculations are based on assumptions suggested to be faulty by Tammela et al. (209) who calculated that 43 patients out of 300 would benefit.

Lim et al. reported results of a prospective study of pretreatment laparoscopic surgical staging in patients with locally advanced cervical cancer. Patients with macroscopic node metastases that were fully resected had a poorer OS rate compared with patients without node metastases. The investigators concluded that the survival benefit of debulking lymph nodes is not clear (210).

Cheung et al. analyzed the therapeutic value of surgically debulking metastatic pelvic nodes. They demonstrated that pelvic control was excellent for both node-positive and node-negative patients. However, frequent distant failures were observed in node positive patients. From these results, they concluded that improving pelvic control by debulking positive pelvic nodes would not translate into improved survival (211).

Another approach for grossly positive pelvic nodes would be radiation dose escalation. Classical radiation dose-response data suggest that approximately 60 Gy is required to control lesions 2 cm in size. Work from Grigsby et al. supports this approach in patients with cervical cancer and grossly involved pelvic lymph nodes (212). By calculating cumulative radiation doses to point P (6 cm lateral to the midline of the patient from a point 2 cm superior to the lateral fornix in the ICBT), they found that only 5 out of 208 patients developed pelvic nodal failure with a mean dose of 67.2 Gy at point P. For 43 patient with PET positive/CT greater than 1 cm (≤ 5 cm) nodes, only 2 (5%) experienced nodal failure. Simultaneous integrated boost IMRT is an encouraging strategy to deliver sufficient dose to positive nodes without substantially increasing doses to surrounding organs.

Invasive Carcinoma Treated by Simple Hysterectomy

Given the frequency of simple hysterectomy or total abdominal hysterectomy (Type I), it is not surprising that occasionally a patient is found to have an invasive cervical cancer unrecognized prior to surgery. Although this occurs uncommonly in an era of cytologic screening, it can occur in patients operated on for what is felt to be carcinoma *in situ*, "microinvasive" disease, or for "benign" indications.

If only microinvasive carcinoma is found, with no evidence of LVSI, no additional therapy is necessary. However, in patients with more advanced disease, simple extrafascial abdominal hysterectomy is not curative, because the paravaginal/paracervical soft tissue, vaginal cuff, and pelvic lymph nodes are not removed.

A number of series have reported results for patients treated with adjuvant postoperative RT in this situation. Favorable outcomes and acceptable levels of toxicity have been reported with this strategy. A series of 90 patients, including 18 stage II patients, treated with RT following inadvertent hysterectomy was reported by Hsu et al. The overall 5-year and 10-year survival rates were 85.5% and 74.1%, respectively. A severe late complication requiring surgical intervention was observed in only 1 patient. They concluded that this strategy provides favorable outcomes (213). Smith et al. also reported favorable results (214).

Another strategy for this situation is to utilize a more aggressive surgical approach, that is, radical parametrectomy (RP). Although it may be technically difficult to perform an adequate radical operation after previous simple hysterectomy, this alternative deserves consideration for selected patients. In an exhaustive review of the literature comparing series of patients having reoperation with RP and pelvic node dissection (LND) versus

those having postoperative RT, the weighted average 5-year survival favored RT (68.7% vs. 49.2%) (215). However, this review included relatively older series. Recently, more promising data have been reported for patients treated surgically. Leath et al. reported good results with the radical surgical approach in 23 stage IA2 and IB1 patients (216). With a median follow-up of 61 months, overall 5-year survival was reported as 96%. There were 7 (30%) operative complications. Buda et al. reported their experience of laparoscopic RP with pelvic lymphadenectomy and partial colpectomy for 12 patients with occult invasive cancer. Three patients received adjuvant treatment (brachytherapy in 1 and CCRT in 2). No intraoperative complication occurred but two patients experienced postoperative complications. At a median follow-up of 50 months, all patients were alive without disease. Despite the small numbers of patients and the possible impact of patient selection, they concluded that this strategy is safe and feasible (217). Park et al. retrospectively evaluated outcomes in 147 patients with occult invasive cancer found after simple hysterectomy (218). Of the 99 patients with IA2–IIA lesions, 26 received no definitive treatment (observation group), 44 received RT or CCRT (RT/CCRT group), and 29 underwent RP (RP group). After a median follow-up of 116 months (range 3 to 235 months), recurrent disease was observed in 0%, 34.6%, 6.8%, and 0% of patients in the IA1, observation, RT/CCRT, and RP groups, respectively. Two patients (27%) had late complications related to RT requiring further management. Five patients in the RP group (17%) experienced perioperative complications which were easily managed, intraoperatively or conservatively. Late complications were not reported in the RP group.

If the postoperative RT approach is employed, treatment should be administered immediately after recovery from the operation, as prognosis is worse if therapy is delayed. When there is any gross tumor present, external RT to the whole pelvis (40 to 45 Gy) is required. In some cases, a small external beam boost might be advisable for an additional 10 to 15 Gy. An intracavitary insertion, as outlined previously, should be performed in most cases. If there is residual tumor, an interstitial implant, when feasible, should be carried out to increase the dose to this volume.

The potential contribution of concurrent platinum-based chemotherapy must be considered, particularly in view of the randomized study of patients treated after RH with high-risk features (142). Although not directly comparable, it is reasonable to extrapolate these results favoring concurrent chemotherapy to patients treated after simple hysterectomy for invasive disease, particularly in patients with gross residual, positive margins, positive nodes, LVSI, and, possibly, adenocarcinoma.

The NCCN guidelines suggest treatment algorithms based on the status of the surgical margins (194). These guidelines suggest that stage 1A1 patients with no LVSI should undergo surveillance. Pelvic RT with concurrent cisplatin-containing chemotherapy with or without brachytherapy is recommended for patients with stage 1A1 with LVSI or with stage 1A2 or higher. If margins are positive and imaging is negative for nodal disease, if margins and imaging are negative in stage 1A2 or greater tumors, options include (1) pelvic RT with (or without) concurrent cisplatin-containing chemotherapy and brachytherapy; or (2) a complete parametrectomy, upper vaginectomy, and PLD with (or without) paraaortic lymph node sampling. In this patient group, those with negative lymph nodes should be observed or treated with pelvic RT with (or without) vaginal brachytherapy if they have high-risk factors, that is, large primary tumor, deep stromal invasion, and/or LVSI.

Stage IIIA Carcinoma of the Cervix

Cervical carcinomas extending to the lower third of the vagina without pelvic sidewall extension or hydronephrosis are uncommon, representing less than 2% of patients with cervical cancer. As a result, these patients are often not reported separately,

although management presents a significant challenge to the radiation oncologist. In general, these patients have a better prognosis than stage IIIB patients, especially when there is limited parametrial extension and the vaginal involvement is continuous with the cervix.

Kavadi and Eifel found a local control rate of 72% in 44 patients, but 5- and 10-year actuarial survival rates were 37% and 34%, respectively, reflecting the impact of distant failure seen in 13 patients. In this series, patients with no parametrial extension and direct extension from the cervix (as opposed to “skip” lesions in the lower vagina) had a 5-year survival of 73%. (219).

The inguinal lymph node areas must be assessed clinically and radiographically. When this assessment is negative, RT is given to the inguinofemoral nodes prophylactically. When the lymph node assessment suggests gross disease, it might be appropriate to confirm this with needle biopsy or consider the role of inguinal lymph node dissection following RT. Alternatively, RT doses can be escalated to reflect the presence of gross tumor. Treating the inguinal nodes adequately while limiting the dose to the underlying femoral heads is a challenge. Considerable appropriate techniques will be described in a later chapter.

More difficult is the challenge of delivering tumoricidal doses of radiation to the entire vagina while respecting tolerances of the normal tissues, in particular the rectum. Given that virtually the entire length of rectum will be treated with an intracavitary approach encompassing the entire vagina, the tolerance will be lessened, and the risk of complications will increase. In addition, because of the typical “slope,” or decrease, in thickness in the superior-inferior direction, there will be a dose gradient that can result in “hot” spots of 120% to 125%. This is potentially remediable with intensity-modulation techniques, although another approach is simply to measure the dose gradient and take it into account by raising the lower border accordingly, and/or taking the gradient into account during the brachytherapy portion of the treatment.

A general approach is to give external beam RT to the pelvis and entire vagina of approximately 40 to 44 Gy over 5 weeks (delivering 50 Gy to the inguinal areas at depth if clinically and radiographically negative), and follow this with 1 or 2 intracavitary implants. An intrauterine tandem combined with Delclos rings permits delivery of a controlled, measurable dose to the vagina (Fig. 21.11). One should aim for a total dose of approximately 65 Gy (LDR or LDR equivalent) to the entire vagina, combining the external and intracavitary doses. One can consider a second implant that does not treat the entire vagina, typically with a Fletcher-Suit applicator, particularly when there is parametrial extension. Ideally, one will deliver 80 to 85 Gy to point A in this fashion, but if the maximum rectal dose is limited to 60 to 65 Gy some compromise in point A dose may be required. These doses are appropriate only for low-dose-rate techniques, which may be preferred when treating the entire vagina. When HDR techniques are employed, greater fractionation will be necessary and tolerance doses will be lower, but with proper care it can be successfully utilized. No matter how the brachytherapy portion of the treatment is done, careful attention to the rectal dose and length of rectum is important. In many cases of IIIA cervical cancer, the tumor will involve only and extend down the anterior vaginal wall, sparing the lateral and posterior walls. When this is the case, the radiation oncologist might consider using smaller vaginal rings (e.g., Delclos rings), and placing packing posterior to the vaginal component of the applicator, in order to further limit the rectal dose. Considerable rectal sparing can be obtained in this fashion. Kazumoto et al. reported a unique ICBT planning program (referred to as “utero-vaginal brachytherapy” [U-V brachytherapy]) and its clinical outcomes for 22 cervical cancer patients including 9 stage IIIA patients (220). With a simple

FIGURE 21.11. Lateral view of an intracavitary implant for a stage IIIA cervical carcinoma with extension to the lower third of the vagina. The tandem extends from the uterine fundus through the vagina. Delclos rings are placed over the tandem throughout its course in the vagina. This controls the distance from the radioactive sources (Cesium-137 in this case) and allows the vaginal radiation doses to be measured and controlled.

determination of the treatment volume, the cervix-parametrium, and the lower vagina were covered automatically and simultaneously by this program. Isodose curves for this program were “galaxy-shaped.” Five-year local-PFS and OS rates were 90.7% and 81.8%, respectively. Among those patients with late complications or morbidity scores higher than Grade 2 Radiation Therapy Oncology Group/European Organization for Research and Treatment of Cancer (RTOG/EORTC), only 1 (4.5%) developed severe proctitis.

It is appropriate to administer cisplatin-based chemotherapy with the external RT with the hope of improving survival. However, concurrent chemotherapy will likely increase acute toxicities, particularly given the increased volume encompassed by the RT port and the sensitivity of the vulva to RT. Considerable individualization of therapy is required.

Small Cell Carcinoma of the Cervix

The term “small cell” should be limited to those rare tumors with counterparts in the lung and other anatomic locations noted for a high proliferation rate, marked propensity to regional lymph node and distant metastases, and positive staining with neuroendocrine markers (221). Epidemiologic analysis using materials identified from the SEER database demonstrated that the mean annual incidence for small cell carcinoma was 0.06 per 100,000 women, compared with 6.6 and 1.2 for squamous cell carcinoma and adenocarcinoma, respectively (222).

Small cell carcinomas are not often confined to the cervix and surrounding tissues at diagnosis. Therefore, workup may include bone marrow aspiration and other tests to detect the metastatic spread characteristic of this histology. Lymph node involvement is present in over 50%, and vascular invasion is frequently present. Viswanathan et al. reviewed 21 patients meeting stringent criteria for neuroendocrine type small cell cervical carcinomas (223). Ten patients had IB1 disease (although 2

of these had radiographic evidence of nodal metastases), and 11 patients had IB2-IIIIB disease. Six patients underwent RH (5 of these were IB1), and 15 patients had RT as curative intent treatment. Cisplatin-based chemotherapy was given to 62%, either neoadjuvantly and/or following surgery or RT. No patient with greater than stage IB1 survived, and even for stage IB1 patients, the survival was much worse than would be expected in more common histologies. In-field RT failures were uncommon, but metastatic failures were not.

Zivanovic et al. analyzed PFS and OS in 17 patients with small cell neuroendocrine carcinoma of the cervix to determine whether platinum-based combination chemotherapy is beneficial (224). In the early-stage disease group, the 3-year distant recurrence-free survival rate was 83% for patients who received chemotherapy and 0% for patients who did not receive chemotherapy as part of their initial treatment ($p = 0.025$). They concluded that the natural history of the patients with small cell neuroendocrine cervical cancer is akin to that of small cell lung cancer, and should be treated with systemic chemotherapy in addition to radiotherapy in early-stage disease.

Cohen et al. reported survival outcomes for 188 patients with small cell carcinoma of the cervix (225). The study population consisted of patients collected from case-series reported in the literature and additional patients treated at their own hospitals. Of 188 patients, 135 had stages I to IIA, 45 stages IIB to IVA, and 8 stage IVB disease. A total of 55.3% underwent surgery, 16.0% had chemoradiation, 12.8% radiation, and 3.2% chemotherapy alone. The 5-year disease-specific survival in stage I to IIA, IIB to IVA, and IVB disease was 36.8%, 9.8%, and 0%, respectively ($p = 0.001$). Adjuvant chemotherapy or chemoradiation was associated with improved survival in patients with stages IIB to IVA disease compared with those who did not receive chemotherapy (17.8% vs. 6.0%; $p = 0.04$). They concluded that use of adjuvant chemotherapy or chemoradiation was associated with higher survival in small cell cervical cancer patients.

Prophylactic cranial RT has also been given following this chemoradiation in the absence of progression. However, its role remains unclear.

Cervical Lymphoma

Lymphomas primarily arising and confined to the cervix are quite rare. Patients often present with signs and symptoms including vaginal bleeding, discharge, and pelvic pain. Cervical lymphomas typically develop and grow submucosally; therefore, Pap smears often do not detect these neoplasms. Generous punch biopsies or conizations are often required for diagnosis. Histologically, these lymphomas are typically of the diffuse, large B-cell variety (226,227).

Due to the rarity of this diagnosis, reports of management approaches are anecdotal and there is no clear consensus. However, general guidelines can be suggested. Clearly, treatment with systemic therapy using combination chemotherapy regimens is indicated in the majority of cases (226–229). The CHOP regimen (cyclophosphamide, doxorubicin, vincristine, prednisone) is commonly used. Surgery has been used as an adjunct to chemotherapy, either before or after chemotherapy, especially in patients with stage I or II disease. Radiation therapy following chemotherapy should be considered, particularly for larger tumors, tumors that do not completely respond to chemotherapy, and in patients with early-stage disease who are not candidates for or who refuse hysterectomy (228,229).

Young patients who wish to preserve fertility can be counseled about the possibility of conization followed by fertility-preserving chemotherapy and close follow-up. Conception has been reported in patients treated in this fashion, although the outcome of these pregnancies is unclear due to their overall rarity (226,230).

Cervical Sarcoma

Primary sarcomas arising in the cervix are exceedingly rare. In a tumor registry of 1,583 patients with cervical malignancies conducted at Washington University, only 8 sarcomas were identified. Five of these were carcinosarcomas. All 6 patients treated with curative intent remained alive with a mean follow-up of 2.5 years, although 2 patients had developed pulmonary metastases. Fadare reviewed uncommon sarcomas of the cervix and reported 11 cases of alveolar soft part sarcoma. All cases seemed to be cured, with varying follow-up periods (231). An additional case of alveolar soft part sarcoma of the cervix, cured by surgery and postoperative RT, was reported by Gitau et al. (232) Radical surgery and chemoradiation were both effective in curing patients with localized pelvic disease (233).

Granulocytic sarcoma can present as a cervical neoplasm. It is important to distinguish this lesion from primary cervical lymphoma, as this is a manifestation of acute myelocytic leukemia and the chemotherapy regimens are quite different. Outcomes for these patients are generally dismal (234).

Carcinoma of the Cervical Stump

Historically, in patients who have undergone subtotal or supracervical hysterectomy, carcinoma of the cervical stump made up nearly 4% of cases treated with RT. Although the incidence has greatly declined, these increasingly rare patients remain at risk of developing cervical carcinoma. The natural history and patterns of spread of these cancers are similar to those of the cervix in the intact uterus. The diagnostic workup, clinical staging, and basic principles of therapy are the same. However, there are potentially important differences in treatment.

Radical operation for stage I cervical stump carcinomas (trachelectomy) is made more difficult by the previous procedure. Barillot et al. prospectively accrued 213 cases of cervical stump carcinoma (235) and reported that stage for stage, local control and survival were equivalent among the surgically treated and the RT-treated patients. However, lethal complications were much more likely in the surgically treated patients. Patients receiving RT including brachytherapy had significantly better results than those having only external RT. Severe complications with RT were similar to those observed among patients with intact uteri.

The higher complication rate probably relates to the lack of adequate uterine cavity length to accommodate a tandem containing 2 or 3 sources. However, some patients with a history of supracervical hysterectomy retain enough lower uterine segment to insert 2 standard cesium-137 sources. As many sources or source positions as technically feasible should be inserted or used in the remaining cervical canal without protruding active source length through the cervical os. Comparably higher activity sources or increased dwell times should be used in the tandem, allowing a greater contribution from these sources to the point A dose and a correspondingly lower vaginal mucosal dose.

In early-stage tumors, it is critical to maximize the brachytherapy portion of the treatment, because this allows higher doses to be delivered to the tumor while limiting dose to normal structures. Early midline shields (MLSs) (e.g., at 20 to 30 Gy) are desirable. Limiting the total external beam dose to 40 Gy, optimizing the intracavitary RT with proper packing and distribution of activity, and respecting the tolerances of the rectum and bladder will keep complication rates reasonably low (Fig. 21.12). Limiting the maximum rectal dose to 65 or 66 Gy and the bladder dose to around 80 Gy (LDR or LDR equivalent) are desirable, even if the point A dose is somewhat compromised (<80 Gy). More advanced stages should be treated with 40 Gy to the pelvis, combined with the maximum intracavitary doses

FIGURE 21.12. Approximately lateral view of intracavitary implant for a cervical stump carcinoma. The intrauterine length is only 2.5 cm, limiting the number of sources or source positions that can be placed into the uterus. The vaginal mucosa, anterior rectal wall, and bladder base will get relatively higher doses for an equivalent point A dose in most cases like this.

permitted within tolerance. Platinum-based chemotherapy will be indicated in most cases. Limited sidewall boosts may be necessary, depending on the dose to the sidewalls from the brachytherapy and the radiographic evaluation of the nodes. When there is no opportunity to insert any sources in the cervical canal, the whole pelvis dose should be increased to 45 Gy, and the primary tumor boosted to around 60 to 65 Gy with shrinking fields. Stereotactic and intensity-modulated RT (IMRT) techniques can be used to escalate doses to the primary tumor.

The 5-year survival for carcinoma of the cervical stump treated with irradiation is similar to that reported for patients with carcinoma of the intact uterus.

MANAGEMENT OF CERVICAL CANCER DURING PREGNANCY

Of all patients with cervical cancer, about 1% are pregnant at diagnosis. Most will present with abnormal cytology or abnormal vaginal bleeding. Overall incidence of abnormal cytology in pregnancy is about 5%. The availability of cervical cytology in developed countries affords an opportunity to diagnose early dysplastic changes during pregnancy, which may contribute to a higher incidence (3:1) of stage I cervical cancer diagnosed during pregnancy compared to the nonpregnant state. Either conventional or liquid-based cytology is effective in pregnancy. The use of an endocervical brush is safe and can enhance the rate of optimal smears. ECC is not recommended due to predisposition to premature rupture of membranes and bleeding.

Hopkins and Morley published their experience with cervical cancer during pregnancy and outcomes compared to those in nonpregnant state (236). They found similar survival rates when controlled for confounding factors such as age and stage.

Diagnosis

All abnormal cervical lesions during pregnancy require a biopsy. Colposcopy in pregnancy is used to rule out invasive disease. Colposcopic evaluation and directed biopsies are safe in pregnancy. In a series of 612 women with abnormal smears during pregnancy reported by Economos et al., 449 colposcopies were performed (237). All patients had satisfactory colposcopy by the 20th week of gestation, as the squamo-columnar junction (SCJ) everts during pregnancy. They reported a 95% concordance rate between colposcopic impression and directed biopsies within one degree of severity. No complications were noted. Failure to visualize the entire SCJ is not an indication to proceed to conization during pregnancy, as most repeat colposcopies will be satisfactory due to eversion of the SCJ as the pregnancy progresses.

A diagnosis of cervical cancer during pregnancy requires a multidisciplinary approach involving gynecologic and radiation oncologists, perinatologist, neonatologist, and psychologic counselors. MRI can be used safely during pregnancy to evaluate spread of disease and lymph nodes. There are reports of laparoscopic staging of lymph nodes during the second trimester as a tool to tailor the decision for treatment, but again there are potential risks with such procedures and treatment decisions should be considered carefully by members of an experienced team (238).

Management of Dysplasia

The progression rate from dysplasia in pregnancy to higher-grade dysplasia in the postpartum period is low, below 10% according to most information. Given these data it is reasonable to manage abnormal cytology in pregnancy according to guidelines in nonpregnant states. Given the low rate of progression and high reliability and safety of colposcopy, a conservative approach is likely to be safe for the patient and the unborn child. Dysplasia diagnosed by colposcopy and biopsies in pregnancy should be followed conservatively with serial colposcopic examinations every 8 weeks and managed definitively in the postpartum period.

Conization During Pregnancy

In an early series of 180 conizations during pregnancy, Averette et al. reported a first trimester fetal loss rate of 24% (239). Second trimester fetal loss was less than 10%. Hannigan et al. reported 13 conizations during the first trimester and no fetal loss. The rate of severe bleeding was 9%. Fetal loss rate in the second trimester was less than 10% (240).

In a small series of 17 patients, Goldberg et al. reported a novel approach to conization in pregnancy. The cervix was injected with vasopressin, and lateral hemostatic sutures and a cerclage were placed following the conization. The mean gestational age was 18.8 weeks (10–32). There was no major bleeding or other complications and no second trimester loss (241). An argument against the use of a cerclage is that the majority of postconization fetal deaths are delayed and presumably due to chorioamnionitis, and not necessarily a function of cervical incompetence. The cerclage may also act as a nidus for infection.

Robinson et al. reported their experience with loop electrocautery excisional procedure (LEEP) excision during pregnancy in 20 patients with gestational ages ranging from 8 to 34 weeks (242). They found that 57% had involved margins and 47% had residual disease after LEEP. There were 3 preterm deliveries, two patients requiring blood transfusions, and one intrauterine fetal demise 4 weeks after LEEP excision (chorioamnionitis was found on autopsy). They concluded that LEEP excision during pregnancy does not yield consistent diagnostic specimens and is

associated with a high complication rate. If conization is indicated during pregnancy, a cold knife technique may be the preferred method. The optimum timing would be sometime in the second trimester.

Treatment of Adenocarcinoma *In Situ* and Microinvasive Disease

Diagnosis of glandular abnormalities in pregnancy can be difficult, as glandular hyperplasia and decidual and glandular cells may exhibit benign Arias-Stella reaction, which may appear ominous to someone who is not experienced with these conditions during pregnancy. An expert evaluation is mandated for accurate diagnosis of glandular disease in pregnancy.

There is a paucity of data on management of AIS in pregnancy. Lacour et al. reported the safety of conization in the second trimester as treatment of AIS in pregnancy in 5 patients. All patients delivered at term, and only 1 required RH for stage IB disease after delivery (243).

It is believed that there is no significant difference in outcome in squamous MID versus AIS. It is difficult to know how to best treat these lesions in pregnancy. It is recommended that similar guidelines be adopted as in nonpregnant patients.

Most patients with MID in pregnancy can be safely followed even if margins are involved with dysplasia (not invasive disease). Vaginal delivery should be safe in women with microscopic disease, and definitive management may be delayed safely until the postpartum period.

Management of Invasive Cancers During Pregnancy

Surgery

Over 70% of cervical cancers in pregnancy present as stage I disease and have an excellent survival rate. Stage, tumor size, nodal status, gestational age, and the patient's desire to maintain the pregnancy are key elements in making therapeutic decisions. Treatment options can be separated according to gestational age of less than 20 or more than 20 weeks.

Invasive disease diagnosed in a pregnant patient of less than 20 weeks gestation should generally be managed immediately, resulting in loss of the fetus. However, there are reports of delaying treatment until fetal maturity without harm to the mother or the fetus. Most of the reported cases of delay in treatment were stage I disease. The delay of treatment ranged from 3 to 32 weeks. The overall mortality is about 5% to 6% with a similar recurrence rate. These data are limited by small numbers of patients but are reassuring when considering a delay in treatment. This approach is appropriate only in selected well-counseled patients with early-stage, small-volume disease.

Patients choosing to delay definitive surgical treatment of stage I disease until after delivery may safely undergo appropriate surgical treatment, including RH. Some data suggest that blood loss and postoperative febrile illness may be increased compared to the normal, non-postpartum patient.

For stage I disease, RH and PL can be safely performed prior to 20 weeks with fetus *in situ* or as a planned procedure after cesarean section in the third trimester after documentation of fetal lung maturity. Excellent oncologic outcomes are generally obtained. There are scattered case reports of treatment of locally advanced disease with NACT using cisplatin alone or in combination with paclitaxel followed by radical surgery after delivery with good results, although there are no large datasets to support routine use (244). NACT can be considered after extensive discussion with mother and family if there is strong desire to maintain the pregnancy despite the diagnosis. The use

of these drugs appears to be safe during pregnancy after first trimester but caution and a careful, multidisciplinary approach are necessary.

Radiotherapy

Most reports of RT or chemoradiation for cervical cancer during pregnancy are in patients with locally advanced disease. NCCN guidelines suggest that patients with early-stage disease have RH and node dissection instead of RT in an effort to avoid radiation fibrosis and to preserve ovarian function (194).

Benhaim et al. reported the use of chemoradiation in 2 pregnant patients (245). The first patient was diagnosed with stage IVA squamous carcinoma at 12 weeks gestation. She was treated with RT and weekly cisplatin with the fetus *in situ*. Spontaneous miscarriage occurred at about 40 Gy, which is consistent with other reports in the literature. The patient died of metastatic disease 20 months after treatment. The second patient was diagnosed with stage IIB squamous cancer at 12 weeks gestation and received the same treatment regimen. Spontaneous miscarriage occurred 3 weeks after beginning RT. The patient remained disease-free at 29 months follow-up. Ostrom et al. reported 2 cases of stage IB2 disease diagnosed at 15 weeks gestational age. Fetal losses occurred 3 to 4 weeks after initiation of RT. Both patients were disease-free 12 months after completing treatment (246). Although experience is limited with chemoradiation in pregnancy, it seems to be feasible and safe. If RT is used in the postpartum setting, it should begin within 3 weeks after uterine involution.

Neoadjuvant Chemotherapy in Pregnancy

NACT in pregnant women with cervical cancer is guided by gestational age at diagnosis, the woman's desire to maintain the pregnancy, stage of disease, lymph node involvement, and histology (247–249). Although rare histologic subtypes such as small cell carcinoma have a poor prognosis and pregnancy termination with immediate treatment is recommended, conventional histologic subtypes including squamous cell, adenocarcinoma, and adenosquamous may be managed without pregnancy termination depending on stage and lymph node involvement (247).

In 2009, a French Working Group and a European International Consensus Meeting published separate guidelines with specific management recommendations (248,249). These guidelines differed slightly. However, they both agreed that for women with cervical cancer who wish to maintain their pregnancy, proper staging with the determination of lymph node involvement was necessary prior to the determination of treatment. Women with Stage IA disease and no lymph node involvement have an excellent prognosis and delayed treatment until fetal maturation is the standard of care. Women with Stage IB1 disease and no lymph node involvement may undergo a RT or proceed with NACT to commence after the first trimester of pregnancy and continue until fetal maturation (247). Women with Stage IB1 with lymph node involvement and those with Stage IB2 or greater disease may also receive NACT to allow for fetal maturation following the first trimester of pregnancy (247). Of the 25 women in the literature treated with NACT (reviewed in, the most commonly used agents were cisplatin alone or in combination with paclitaxel (247). No infant was reported to have abnormalities, with follow-up ranging from birth to 80 months. Interestingly, Marnitz et al. (244) evaluated cisplatin concentrations in the mother and fetoplacental compartment of 7 women with cervical cancer, and noted significantly lower levels of cisplatin in umbilical cord blood and amniotic fluid compared with maternal blood, suggesting that NACT may be safely given. Although the literature is limited and long-term follow-up lacking, neoadjuvant platinum-based chemotherapy in pregnant

women with cervical cancer appears to be feasible and safe for both the mother and infant.

Radical Trachelectomy During Pregnancy

Vaginal or abdominal trachelectomy and cerclage placement along with laparoscopic or pelvic lymphadenectomy is an option for treatment of stage I cervical cancers less than 2 cm in women interested in preserving pregnancy and fertility (173). Ungar et al. reported birth of 2 healthy term infants to 2 of 5 pregnant patients with stage IB disease who were so treated (176). Gestational age ranged from 13 to 18 weeks. Fetal losses were reported on postoperative days 1 and 16. All patients remained disease-free with follow-up ranging from 10 to 54 months.

Recently 2 case reports demonstrated successful treatment of stage IB cervix cancer during pregnancy at 16 and 16 weeks with abdominal and vaginal trachelectomy, respectively, with completion of pregnancy at term (250,251). It is important to note that these are highly selective cases performed by a multidisciplinary team with high level of expertise and should be considered investigational.

Route of Delivery

Sood et al. studied outcomes of women diagnosed with cervical cancer during pregnancy or within 6 months after delivery. One of 7 women who had cesarean sections developed local and distant metastasis compared to 10 of 17 (59%) of those who delivered vaginally. In multivariate analysis, vaginal delivery was the strongest predictor of recurrence. They concluded that pregnant women with cervical cancer should delivered by cesarean section (252).

Except in stage IA1 where vaginal delivery is reasonable, a cesarean section should be performed in the presence of cervical cancer. This should be done through a classical uterine incision to avoid encroaching into the lower uterine segment or cervix. In addition, cesarean section can be followed by RH as definitive treatment or to allow surgical exploration to delineate extent of disease. Performing oophorectomy during the procedure may assist in preserving ovarian function after pelvic RT.

HUMAN IMMUNODEFICIENCY VIRUS/ACQUIRED IMMUNODEFICIENCY SYNDROME, AND CERVICAL NEOPLASIA

About 2.1 million people live with HIV in North America, of whom approximately 1.2 million are in the United States. Heterosexual transmission accounts for 34% of cases. The proportion of women among new HIV and AIDS diagnoses has increased greatly in the United States. Over 50% of HIV-positive women are also infected with HPV. In 1993, the CDC designated high-grade dysplasia as a marker for early HIV infection and cervical cancer as an AIDS-defining illness (253).

Prevalence

Ahdieh et al. reported that the HPV point prevalence in HIV-positive women is as high as 60%, compared to about 30% in HIV-negative women (254). The relative risk (RR) of HPV-associated cancers in patients with HIV/AIDS is significantly increased, with a relative risk of over 5. The clearance of HPV in an HIV-positive individual correlates directly with the CD4 count. HPV DNA prevalence is as high as 85% in those with CD4 counts of 0 to 500 and as high as 70% in those with CD4 counts over 500. This is compared to a range of 30% to 50%

in HIV-negative women. Even with a normal CD4 count, HIV-positive women still have a twofold increase in incidence of HPV compared to HIV-negative women (255).

Pathophysiology

In HIV-infected women with no evidence of CIN on Pap smear and colposcopy and negative HPV testing, the probability of developing CIN is much greater than in women who are HIV-negative (20% vs. 5%). The strongest predictor of development of CIN in HIV-positive women is the degree of immunosuppression delineated by CD4 counts (255). When matched for sexual behavior, HIV-positive women have a one- to twofold increase in HPV sero-prevalence compared to HIV-negative women. When controlled for exposure to HPV, the persistence and detection of HPV is much greater in HIV-positive women compared to HIV-negative women (256–258). In immunocompetent women, the rate of HPV clearance within 2 to 4 years is 80% to 90%. This is affected by multiple factors such as smoking, re-exposure, prolonged oral contraceptive use, and other sexually transmitted infections (e.g., *Chlamydia trachomatis*, herpes simplex virus). The clearance rate of HPV is twofold greater in HIV-negative women as compared to those infected with the virus, despite adequate CD4 counts and low HIV viremia (256,258,259). Infection of vaginal Langerhans cells (LC) by HIV is a primary mode of entry and propagation into systemic infection. LCs constitute an important local defense against HPV infection. The numbers of LCs are lowered significantly in patients with AIDS with a resultant decrease in their immunologic response to HPV.

HPV Genotype Distribution in HIV-Positive Women

Most HIV-positive women are infected with multiple types of high-risk HPV including 11, 16, 18, 33, 51, 52, 53, 58, and 61. Clifford et al. found HPV-16 to be the most common HPV subtype in HIV-positive women; however, when compared to HIV-negative women the rate of type 16 infection is lower and type 18 may be more prevalent (260). HIV-positive women showed a higher proportion of multiple and HPV types other than 16 as compared to HIV-negative women.

Screening

Despite conflicting reports in the literature regarding the reliability of cervical smears as a screening tool for CIN in HIV-infected patients, it remains an important tool in primary screening. In a study of 189 HIV-infected women versus 95 controls, Anderson et al. found that the incidence of biopsy-proven CIN, despite normal cytology, was greater for HIV-infected women (14.3% vs. 1.2%, $p < 0.01$) (261). However, in the small number of HIV-infected women with normal cytology and biopsy-proven CIN, 95% had an abnormal cytologic smear within the preceding 12 months, most commonly ASCUS. Even after treatment for cervical dysplasia, over 40% will have persistent cytologic abnormality, with most being low-grade CIN 1. The authors concluded that these data did not support routine colposcopy in all HIV-infected women. These data also highlight the importance of vigilance in follow-up and colposcopic examination of even low-grade cytology including ASCUS in HIV-infected women, especially those with low CD4 counts. A finding of ASCUS on cervical smears of HIV-infected women is more common than in uninfected women. The probability of development of CIN in those with ASCUS was greater in the infected group compared to controls (60% vs. 25%) (262). According to USPSTF recommendations, women with HIV infection should undergo

semiannual screening in the first 12 months after diagnosis, and then annually if the results are normal. If any abnormality is detected, then closer follow-up and colposcopic examination are warranted.

In a low-resource setting where cervical cytology and adequate follow-up is problematic, a new approach has been devised and tested called the “see and treat,” or visual inspection with acetic acid (VIA), or visual inspection with Lugol’s iodine (VILI). In this approach, health care extenders are trained to use immediate visual inspection to detect dysplastic changes on the cervix. If detected, immediate treatment of the area with cryotherapy is offered. Multiple studies addressing the accuracy of VIA demonstrated a sensitivity of 66% to 96% with median of 84% and a specificity of 64% to 98% with median of 82%. The positive predictive value was 10% to 20% with a NPV of 92% to 97%. Overall VIA is found to be more sensitive but less specific than cytology. The overall sensitivity and specificity of VIA and VILI are 92% and 85%, respectively. Although these methods can be helpful in a low-resource setting, debate continues on their use in HIV-positive women.

HPV Subtype Testing

Given the high prevalence of HPV in HIV-infected women, the value of HPV testing is unclear. Adding HPV testing to the initial 2 cervical cytologies in the first year after diagnosis of HIV may modify subsequent cytology screening intervals, and may be cost-effective in patients with CD4 counts greater than 500 with normal cytology whose risk would be equivalent to women without HIV infection. There is no consensus regarding its use, and the best recommendation is to individualize testing to the patient and specific risk factors.

Vaginal Cytology After Hysterectomy

There is a paucity of data regarding cytologic screening of the vaginal vault in women infected with HIV. Paramsothy et al. evaluated 102 HIV-infected women after hysterectomy for varying indications (263). Among those with a history of CIN prior to hysterectomy, 63% were found to have vaginal intraepithelial neoplasia (VAIN) in follow-up. CD4 count of less than 200 and HIV viral load of greater than 10,000 copies/mL at time of hysterectomy were highly predictive of subsequent VAIN. Overall, out of 102 women, 16% developed VAIN in follow-up. The authors concluded that close follow-up with vaginal cytology is warranted in HIV-infected women after hysterectomy, particularly in those with severe immunodeficiency and a previous history of CIN. A more recent study by Massad et al. evaluated 335 HIV-positive and 75 HIV-negative patients with vaginal cytology after hysterectomy for prior cervical dysplastic disease. Over 5.6 years, 29% of HIV-positive patients had abnormal cytology versus 4% of controls. The most common abnormality was ASCUS and LGSIL. The incidence of VAIN 2 or worse was 0.2% in the HIV-positive population versus 0.01% in the control arm. Two HIV-positive patients developed vaginal cancers treated successfully with radiation. The severity of vaginal dysplasia was related to the CD4 count (264).

Effects of Highly Active Antiretroviral Therapy on HPV

The introduction of highly active antiretroviral therapy (HAART) has made a significant impact on the prognosis of patients with HIV, but it has not been shown to affect the rate of HPV detection, and data regarding its effect on cervical dysplasia are mixed. The close relationship of low CD4 count and cervical dysplasia makes HAART attractive in halting progression of HPV infection.

Ahdiel-Grant et al. studied 2,059 HIV-infected women receiving HAART (265). In 312 women with CIN, 141 had regression of CIN to normal with a median time to regression of 2.7 years. After HAART, elevated CD4 counts were associated with greater regression of CIN. However, there are no clear data to support HAART's role in regression of high-grade dysplasias. Therefore, the recommendation remains active surveillance and aggressive treatment for HPV in HIV-positive women who have responded well to HAART with low viral loads and adequate CD4 levels. Omar et al. studied 2,325 women in South Africa and noted a low risk of regression to normal of high grade and low grade disease in HIV-positive patients. HAART therapy appeared to protect against progression (266).

HPV Vaccination and Its Effect on HIV-Positive Women

In Phase 3 clinical trials, HPV vaccination has been shown to be effective in reducing the rate of HPV infection by over 90% by inducing a much higher antibody titer for almost 5 years, compared to the natural immune response (267,268). None of these trials included women known to have HIV infection, and data demonstrating the efficacy of HPV vaccines in HIV-positive women are lacking. A trial of HPV vaccination in HIV-positive men demonstrated a high rate (>90%) of seroconversion to types 16 and 18 without any adverse effect on CD4 counts or viral load (269). Another published study of HPV vaccine in an HIV-positive population was in children between 7 and 12 with CD4 counts greater than 15 who were stable. The quadrivalent HPV vaccine was safe and immunogenic in this patient population, and no effect was seen on the CD4 counts or the plasma HIC RNA (270).

Larger studies in women evaluating for effects on dysplasia are pending.

Treatment of Dysplasia

The indolent nature of low-grade CIN in HIV-positive women allows for a conservative treatment approach. These patients have a low rate of progression to high-grade CIN, especially if CD4 counts are above 500. Delmas et al., in a large study of the natural history of CIN in HIV-positive women, demonstrated that almost 30% of low-grade CIN lesions would regress (271). Close follow-up with cytology or colposcopy every 4 months will help in detecting progression. It is important to collaborate with other health care professionals caring for the patient, particularly to determine the CD4 count status. As mentioned, HAART therapy may also contribute to regression of low-grade CIN.

For high-grade CIN, cervical conization by cautery or cold knife technique, or ablative techniques such as cryotherapy or laser vaporization are adequate, provided that invasive disease has been ruled out and that a satisfactory colposcopy is documented.

Although these techniques are effective in treatment of CIN in patients with HIV, the rate of recurrence is higher than in HIV-negative women. Wright et al. reported outcomes from LEEP procedures, finding a recurrence rate of 56% in patients with HIV versus 10% in HIV-negative patients (272). The quality and size of the LEEP was an issue, as all HIV-positive patients had positive margins compared to only 32% of controls. However, even when controlling for margin status, the rate of recurrence was higher among HIV-positive women, highlighting other risk factors for disease recurrence; for example, CD4 counts.

Role of Medical Therapy

Maiman et al. evaluated 5-fluorouracil (5-FU) as maintenance therapy in HIV-positive women after treatment for high-grade

dysplasia (273). Women received either biweekly 5-FU (2 g) or no further therapy. The recurrence rate was 28% in the treatment arm compared to 47% in the observation arm. Those with CD4 counts less than 200 had a 46% recurrence rate versus 33% in patients with CD4 counts greater than 200. There was no grade 3 or 4 toxicity.

Robinson et al. studied the effects of isotretinoin for low-grade dysplasia in women infected with HIV and found no significant effect on time to progression (274).

Treatment of Invasive Cancer

The age at which HIV-infected women present with cervical cancer is, on average, 15 years younger than HIV-negative cohorts. Lomalisa et al. found that CD4 <200 was an independent risk factor for advanced stage of presentation (275). The treatment of invasive cervical cancer in HIV-infected women differs little from that used in HIV-negative women. There is little data on the role and long-term follow-up of RH for early-stage disease. Gichangi et al. evaluated the impact of HIV status on morbidity and pelvic tumor control following pelvic RT and found that 53% had acute radiation-related grade 3 to 4 toxicity (276). HIV infection was associated with a sevenfold higher risk of multisystem toxicity, and was found to be a major factor in treatment interruption; it was also associated with a sixfold increased risk of residual tumor 4 to 7 months after treatment. Mugambe and Kavuma compared outcomes of HIV-infected women with cervical cancer treated with RT, finding that 4-year survival was significantly lower for sero-positive patients as compared with sero-negative (277). Simonds et al. evaluated 59 HIV-positive versus 324 HIV-negative patients with stages IB to IIIB treated with chemo-radiation. They found that only 53% of HIV-positive patients completed treatment compared with 74% of HIV-negative controls (278). Further studies are needed to address the specific challenges of treating HIV-positive patients with cervix cancer with chemo-radiation.

SURGERY

A generally accepted classification of types of hysterectomy is given in Table 21.3 and described below.

Class I: Extrafascial Hysterectomy

This is the most common hysterectomy performed for a variety of gynecologic disorders. It consists of removing the uterus by separating it from the adnexal structures and round ligaments, dissecting the bladder off of the vesicouterine fold past the level of the cervix, ligation of the uterine vessels at their insertion close to the cervicouterine junction, serial application of surgical clamps next to the uterine and cervical wall as the parametrial tissues are separated from these walls, and completed by removal of the cervix off the upper vaginal vault with sparing as much vaginal tissue and length as possible. The pubovesico-cervical fascia is removed with the uterus. The opened vaginal cuff is usually closed with simple running or interrupted sutures. This hysterectomy is adequate for treatment of stage IA1 and advocated by some for stage IA2. This procedure can be accomplished abdominally, vaginally, laparoscopically, or by robotic assistance technology.

Class II: Modified Radical Hysterectomy

The modified radical hysterectomy (MRH) has gained popularity as the operation of choice for treatment of early-stage cervical

Table 21.3 Types of Abdominal Hysterectomy

Type of Surgery	Intrafascial	Extrafascial Type I	Modified Radical Type II	Radical Type III
Cervical fascia	Partially removed	Completely removed	→	→
Vaginal cuff removal	None	Small rim removed	Proximal 1–2 cm removed	Upper one-third to one-half removed
Bladder	Partially mobilized	→	→	Mobilized
Rectum	Not mobilized	R-V septum partially mobilized	→	Mobilized
Ureters	Not mobilized	→	Unroofed in ureteral tunnel	Completely dissected to bladder entry
Cardinal ligaments	Resected medial to ureters	→	Resected at level of ureter	Resected at pelvic sidewall
Uterosacral ligaments	Resected at level of cervix	→	Partially resected	Resected at postpelvic insertion
Uterus	Removed	→	→	→
Cervix	Partially removed	Completely removed	→	→

Note: Type IV, extended radical hysterectomy (partial removal of bladder or ureter), in addition to type III.

cancer, depending on extent of the lesion. MRH involves opening the paravesical and pararectal spaces to determine resectability of the tumor with the goal of obtaining adequate negative surgical margins. This is accomplished by palpating the parametrial tissues and surrounding structures by placing the index finger in the paravesical space and the middle digit in the pararectal space to feel the parametrium directly. The pelvic nodal tissues are examined for gross involvement. Once resectability is established, the rest of the operation is carried forward.

MRH involves dissection of the uterine artery at its junction with the ureter. The ureters are partially dissected off the parametrial tissue and tunneled to their insertions into the bladder. The bladder is dissected off the lower uterine segment past the cervix. The parametrial tissue is resected medial to the ureter. The ureterosacral ligaments are isolated, and the proximal portions medial to the ureter are resected. A 1- to 2-cm vaginal margin is resected along with the cervix. A PL is typically performed along with MRH. Type II MRH is reserved for microscopic or smaller tumors (<2 cm), depending on the surgeon's experience and preference.

Class III or Radical Abdominal Hysterectomy

The RH differs from the MRH in the extent of dissection and resection of parametrial tissue. The paravesical and pararectal spaces are opened in a similar fashion as the MRH. The uterine artery is ligated this time at its origin from the anterior division of the internal iliac (hypogastric) artery. The ureters are dissected with complete tunneling to their insertion into the bladder trigone. The ureterosacral ligaments are isolated after the rectovaginal space is developed. The bladder is dissected off the cervix anteriorly. The cardinal ligaments are resected to the pelvic sidewall. Complete resection of the ureterosacral ligaments to their attachment may not be necessary in all cases. An alternative is resection of the ureterosacral ligaments midway and resection of 2 to 3 cm of proximal vagina, but the operation can be tailored according to tumor size and patient's anatomy.

The choice of abdominal incision for RH depends on body habitus. A Maylard incision keeps the fascia on the rectus muscles. The epigastric vessels are ligated and the muscle is transected in the middle to have greater access to the sidewall and to facilitate PL. The other option is a Cherney's incision, which involves detachment of the rectus muscle from its tendinous insertion,

allowing for greater access to the pelvis and common iliac and lower paraaortic nodes. The muscle is reattached to the tendon that is inserted into the symphysis at the end of the procedure. The peritoneum is closed in both of these approaches. In properly selected patients, these incisions provide excellent exposure compared to a vertical incision with better cosmetic outcome and perhaps less discomfort to the patient. Both MRH and RH can be performed by minimally invasive approach using laparoscopic and robotically assisted methods. The advantages of these approaches such as less pain, length of stay, and faster recovery has made them more popular in the last few years. It is important to note that the approach must be tailored to the patient's clinical situation and the surgeon's experience and expertise (279).

Class IV or Extended Radical Hysterectomy

There is little indication for extended radical hysterectomy (ERH) with availability of modern RT and chemosensitization for locally advanced tumors. As distinct from Type III RH, ERH involves complete dissection of the ureter off the vesicouterine ligament, sacrifice of the superior vesical artery, and resection of three-fourths of the vagina. The risk of bladder dysfunction and fistula formation is greatly increased compared to Types I to III hysterectomy.

Class V: Hysterectomy

A rarely performed operation, a Type V hysterectomy involves resection of the distal ureter or bladder with reimplantation of ureter if needed.

New Classification of Radical Hysterectomy

In 2008, a new proposed classification of RH was presented based mainly on the lateral extent of the resection (280). There are four types (A–D). Type A is an extrafascial hysterectomy. The paracervix is transected medial to the ureter. The uterine vessels are ligated at the insertion of the cervico-uterine junction and minimal vagina is removed.

Type B involves transection of the paracervix (parametrium) at the level of the ureter, and there are 2 subtypes. Subtype B1 is Type B without removal of the lateral paracervical lymph nodes. Subtype B2 includes removal of the lateral paracervical lymph nodes. The ureter is dissected from the tunnel under the uterine artery and vein and rolled laterally. The paracervix is then resected at the level of the rolled ureter. A 1- to 2-cm vaginal margin is obtained. This classification is similar to a modified or a Type 2 RH as described previously.

In a Type C RH, the paracervix is resected at a more lateral margin next to the hypogastric vessel. It also has 2 subtypes: C1, with nerve preservation, and C2, without nerve preservation. The uterosacral ligaments are resected close to the rectum. The ureter is completely mobilized and the paracervix is removed closer to pelvic sidewall close to the hypogastric vessels. The uterine vessels are ligated at their origin. Preservation of the hypogastric plexus is highlighted in this category (C1), which differentiates it from the classical Type 3 RH as previously described. The bladder branches of the plexus near the bladder pillars are preserved.

In a Type D RH, the entire paracervix is removed. Again, there are 2 subtypes. Subtype D1 constitutes removal of the entire paracervix with the hypogastric vessels. Subtype D2 is similar to D1, with the additional removal of fascial and muscular structures. These are rare operations, with type D1 removing the entire paracervix at the pelvic sidewall with the hypogastric vessels with view of the exposed sciatic nerve. D2 includes D1 with further extension of adjacent fascial and muscle resection. This corresponds to a radical procedure called a laterally extended endopelvic resection (LEER).

Radical Vaginal Hysterectomy

The first description of performing a RH through a vaginal approach dates back to early 20th century. The procedure had fallen out of favor due to the introduction of pelvic lymphadenectomy for management of cervical cancer and the inability to perform this component vaginally. With the introduction of laparoscopic lymphadenectomy, RVH has gained greater acceptability in the oncology community, and many centers are now offering that as an alternative to radical abdominal hysterectomy (RAH). The main advantage of minimally invasive surgery is the omission of the abdominal incision, hence a quicker and less painful recovery.

The technique for RVH starts with a LPL. The paravesical and pararectal spaces can be opened laparoscopically in a similar fashion as described during a RAH. The vaginal approach begins with demarcation of about 1 to 2 cm of vaginal margin with a circumferential incision around the vaginal mucosa and its separation from the cervix. The vaginal mucosa is then folded over the cervix and used as an anatomic marker, and is helpful in downward traction of the specimen. The vesico-uterine space is then opened and the bladder pillars identified and ligated. The paravesical space is further explored with digital dissection, and the ureters are palpated and identified. The uterine vessels are now identified and ligated at their origin from the hypogastric vessels. Attention is then turned to the posterior portion, where the pouch of Douglas is opened, and the uterosacral ligaments are then identified and ligated midway. The ureters are further retracted laterally, allowing for resection of the parametrial tissues. The specimen is then released and removed. The vaginal cuff is then closed in the usual fashion with delayed absorbable sutures.

Radical Trachelectomy

Great care must be exercised to assure proper selection of the right candidate. This procedure is generally recommended for

patients with tumor sizes less than or equal to 2 cm. There should be no endocervical lesion or extension, and workup for metastatic disease should be negative, including nodal basins. Currently no histologic type is seen as a contraindication, although some view glandular lesions as more risky. The procedure can be done abdominally or vaginally. The vaginal approach has gained greater popularity due to benefits of minimally invasive surgery. The procedure has been described as performed robotically, although large data sets are not available.

For RVT, a LPL is performed. The vaginal component begins as the RVH with delineation of 1 to 2 cm of vaginal margin and a circumferential incision to separate the vaginal from cervical mucosa. The spaces are opened in a similar fashion as an RVH. The main difference is the preservation of the uterus by amputating the cervix off the cervico-uterine junction. Usually about 1 cm of cervix is left. A frozen section may be used to determine that the endocervical margin is free of tumor. Once complete resection is secured, a cerclage is placed around the cervico-uterine junction. A probe is placed into the remaining endocervical canal to prevent a tight closure, thereby preventing cervical stenosis. The posterior cul de sac is then closed. The remainder of the vaginal cuff is sewn to the uterine stump in an interrupted manner. Patients are followed with cytology and clinical examination as per protocol.

Nerve-Sparing Radical Hysterectomy

RH can disrupt the hypogastric plexus, which contains sympathetic fibers that fuse with parasympathetic fibers located in the parametrium to control bladder contraction and compliance. Bladder dysfunction occurs in about 5% of patients, which may require continuous or intermittent drainage for several weeks. Some patients may also experience some rectal dysfunction, depending on the extent of the dissection and resection. Nerve-sparing radical hysterectomy (NSRH) has been proposed as a possible technique to identify and spare nerves and preserve good oncologic outcomes (281–283).

NSRH is described as identification of the hypogastric nerve beneath the ureteral sheath lateral to the ureterosacral ligament, identification of the inferior hypogastric plexus during resection of the cardinal ligament, and preservation of the distal inferior hypogastric plexus during dissection of the posterior aspect of the vesicouterine ligament.

Although intriguing, large studies to clearly define the benefit of NSRH are lacking. Most studies are small series, but there are some data suggesting the benefit of preserving urinary function without compromising the oncologic outcome (281). Charoenkwan et al. reported on postvoid residual (PVR) of patients with NSRH versus standard RH (282). At 7 days, 36% and 27% of NSRH patients had PVRs less than 100 and less than 50 cc, respectively, increasing to 82% and 77% by day 14. Raspagliesi et al. reported that Type III NSRH had a similar rate of bladder dysfunction as MRH, and both were lower than standard RH III (283).

Minimally invasive NSRH has been described and feasibility confirmed (284). Magrina et al. investigated the feasibility of robotic nerve-sparing hysterectomy in a small number of patients and found that this technique could be performed using the robotic platform, without compromising radicality of the operation (285).

Pelvic Exenteration

Although total pelvic exenteration (TPE) has been employed in selected patients with stage IVA cervical cancer, it is mainly used for patients with limited central recurrences and no metastatic disease following treatment with primary RT or combined surgery and RT. It involves *en bloc* removal of bladder, uterus, rectum, vagina, and, at times, vulva, depending on the exact

site and extent of recurrence. The procedure can be tailored to remove only the anterior or posterior structures, including the bladder (anterior exenteration) or rectum (posterior exenteration). In treatment of central recurrence of cervical cancer, TPE is the most common approach. Reported survival rates are quite variable, possibly due to varying follow-up intervals, patient selection factors, and whether the cohort includes patients in whom the exenteration was attempted but abandoned.

As part of TPE, reconstruction can involve diversion of the urine through a conduit utilizing a segment of the bowel (ileum, transverse, and sigmoid colon) and/or vaginal and pelvic reconstruction with placement of flaps using either transposed muscle (rectus or gracilis), segments of colon (rarely), or omentum. Depending on the location of tumor and the extent of resection, the colon may be reanastomosed with the rectal stump (supralevator) or a permanent colostomy placed.

TPE is a morbid operation that should only be undertaken in selected patients with limited recurrences. Sidewall extension, metastatic disease, and, usually, hydronephrosis are possible contraindications to the procedure. Even with appropriate workup and evaluation, a significant minority of candidates will have the procedure aborted due to intraoperative findings of metastatic or locally advanced disease. Limited data suggest that the use of PET/CT technology may assist in detecting occult metastatic disease prior to consideration of TPE (286). Equally important are evaluations of patients' overall health status, and a careful psychological and social evaluation and counseling to ensure that the patient realizes the sequelae of TPE. Perioperative complications can include bleeding, infection, cardiac and pulmonary complications, gastrointestinal and urinary leaks, fistulas, bowel obstruction, and reconstruction flap failure. Sexual dysfunction and psychosocial effects are often longer-term sequelae that can be permanent.

RADIATION THERAPY

External Irradiation

Standard Fields (Whole pelvic radiotherapy, Non-IMRT)

Treatment of invasive carcinoma of the uterine cervix requires delivery of adequate doses of RT both to the primary disease

(including surrounding at-risk tissues) and the pelvic lymph nodes. Treatment portals of whole pelvic RT have historically been designed in reference to pelvic bony structures as an anatomic surrogate (287) reported on intraoperative retroperitoneal measurements carried out in 100 patients at the time of radical surgery. Both common iliac bifurcations were cephalad to the level of the lumbosacral prominence in 87% of patients. Therefore, the superior border of the pelvic portal should be at the L4–5 interspace if the intention is to include the external iliac and hypogastric lymph nodes. This margin should generally be extended to the L3–4 or even the L2–3 interspace if common iliac nodal coverage is indicated. The width of the pelvis at the level of the obturator fossae averaged 12.3 cm, and the distance between the femoral arteries at the level of the inguinal rings averaged 14.6 cm. Posterior extension of the cardinal ligaments in their attachment to the pelvic wall was consistently posterior to the rectum and extended to the sacral hollow. The uterosacral ligaments also extended posteriorly to the sacrum. These anatomic landmarks must be kept in mind in the correct design of lateral pelvic portals, particularly in patients with stage II or higher lesions. It is also important to recognize that ligamentous tumor extensions may be present but unrecognized, even with modern imaging.

Standard pelvic portals based on bony structures are as follows (Fig. 21.13). For anteroposterior–posteroanterior (AP–PA) fields, the superior border should be between L4 and L5, the lateral border should be 1 to 2 cm lateral to the true pelvic diameter, and the inferior border should be at the lower extent of the obturator foramen at least 4 cm below the inferior extent of disease. For the lateral fields, superior/inferior borders should be identical to AP–PA fields, the anterior border should slightly anterior to the symphysis pubis and at least 1 to 2 cm anterior to common iliac nodes. It is advisable to include the uterine fundus in the treatment volume, by employing imaging techniques such as CT/MRI. Routinely placing the posterior border at the S2–3 interspace frequently results in inadequate coverage of the planning target volume. For patients with advanced disease, the posterior border should be placed behind the anterior surface of the sacrum. When there is vaginal involvement, the field should extend distally beyond the tumor a minimum of 4 cm, although some contend that the entire length of vagina should be treated down to the introitus.

The use of pelvic bony structures to design treatment portals has the advantages of being relatively simple to reproduce and will, in the majority of cases, include all gross tumor and likely

FIGURE 21.13. Standard fields for external beam whole pelvic radiation therapy. **A.** Antero-posterior port. **B.** Lateral port.

routes of local and nodal spread. However, it runs the risk of geographic misses, similar to overly restrictive CT volumes. Bonin et al. analyzed the 2-D simulation films (after lymphangiogram) of 22 patients to determine whether standard pelvic fields as defined by the GOG adequately cover regional nodes (288). They demonstrated that 10 of 22 (45%) patients would have had inadequate nodal irradiation if their fields had been designed according to standard GOG parameters. In all cases, these incompletely irradiated lymph nodes were from the lowest of the lateral external iliac group.

Groin Irradiation

In patients with involvement of the distal third of the vagina, portals should cover the inguinal lymph nodes because of the increased probability of metastases. Understanding the location of the inguinal nodes is best accomplished by measuring the depth of the femoral vessels by cross-sectional imaging. The depth of these nodes averages 6 cm and can vary substantially and be beyond the range of typical electron energies. Dittmer and Randall have published a convenient method of treating inguinal-femoral nodes using AP-PA photons only while limiting the dose to femoral heads and avoiding some of the problems with junctioning fields, for example, electrons (289). Moran et al. reported their institutional clinical experiences of modified segmental boost technique (MSBT), as well as a dosimetric comparison of the MSBT and IMRT (290). Alternatively, IMRT approaches can be used (291).

Use of Midline Shield

Although common practice, there is no consensus regarding the use of MLSs during external beam RT for cervical cancer, resulting in variability in opinions and practice patterns (292,293). The purpose of the MLS is to limit dose to the bladder and rectum in order to permit maximization of the intracavitary dose, while still delivering sufficient doses to gross parametrial disease and microscopic or gross pelvic sidewall disease (nodal or tumor extension). By allowing a greater contribution of dose from the intracavitary portion of the treatment, dose escalation results from the higher doses delivered interior to the typical point A isodose. This form of dose escalation takes advantage of the inverse square law to further limit dose to bladder and rectum.

In general terms, patients with earlier disease (stages I to IIA, or perhaps early IIB) are most likely to benefit from earlier introduction of an MLS (20 to 30 Gy); patients with more advanced disease should not have an MLS placed before 36 to 40 Gy, and possibly not at all. By performing pelvic examinations on a weekly basis in patients receiving primary RT for cervical cancer, the physician might note an early favorable response that might permit earlier use of the MLS. Keeping in mind the purpose of the MLS, a frequent practice is to use a standard-width shield (4 cm), and place it in midline position. Generally, the pelvic dose delivered with the MLS in place is not added to the point A dose, but this dose is added to the nodal (sidewall, point B, point P) dose calculation. Unilateral sidewall boosts should be considered in patients who have only unilateral parametrial or sidewall involvement. Increasing parametrial doses correlates with risk of complications, particularly radiation proctitis.

Although some investigators express objection to the physical/clinical reliability of the use of MLS (294), excellent treatment outcomes have been recently reported, consistent with the long history and positive results from their use (295).

Small Field RT

The pelvis is by far the most frequent site of failure in localized cervical cancer patients, regardless of the initial treatment.

However, in node-negative patients, the risk factors that indicate adjuvant RT following radical surgery are overwhelmingly related to a risk of failure in the central pelvis, including the vaginal vault and paravaginal soft tissues. Given the well-known relationship between radiation volume and complication risk, Kridelka et al. limited the adjuvant pelvic RT to fields smaller than “standard” (296). In 25 patients with a risk of recurrence of at least 40%, as suggested by GOG criteria (101), only one recurrence was noted, with a median follow-up of 32 months. As predicted, morbidity was very limited in quantity and grade.

A similar experience with small field pelvic RT was reported by Ohara et al. in 42 patients with stages I–II node-negative squamous carcinoma of the cervix at significant risk of local recurrence (297). All patients so treated had deep cervical stromal invasion, parametrial extension, and/or positive or close (<5 mm) surgical margins. Only 3 patients treated with small field RT suffered recurrences, all in the pelvis. Serious toxicity was rare. Oike et al. evaluated the potential dosimetric advantage of small pelvic fields excluding common iliac region with 4-field-box technique (M4F). They demonstrated that the M4F plan was significantly better in limiting dose to both small bowel and sacrum (298). Planning CT and MRI images were used to precisely delineate the “small pelvic field” clinical target volume (CTV).

Using the Delgado GOG score (101), Yeo and colleagues developed criteria for tailored adjuvant RT in node-negative stage IB–IIA cervical carcinomas. Patients with a GOG score less than 40 received no RT, while patients with scores of 40 to 120 and greater than 120 received small field RT and standard pelvic RT, respectively. With a median follow-up of 57 months, the 5-year DFS was 98.2% and there were no grade 3 to 4 toxicities. Interestingly, lower limb lymphedema was significantly less with small field RT compared to standard pelvic RT (299).

An alternative approach to limit small bowel dose in the post-operative RT setting is to utilize IMRT approaches, as described in the next section.

Intensity-Modulated External Radiation Therapy

Significant developments in the technology of radiotherapy equipment (e.g., linear accelerators, multileaf collimation, treatment planning systems) have enabled delivery of highly precise external radiotherapy, utilizing a technique known as IMRT. IMRT refers to the delivery of multiple radiation beams with varying intensity patterns that, when summed inside the patient, create a dose distribution in which the target receives the prescribed dose (with some heterogeneity) while tissues that are to be avoided receive much less radiation. Treatment planning is based on 3-dimensional imaging utilizing CT, most commonly. MRI and PET images can also be incorporated into the determination of treatment volume.

Specially configured linear accelerators with multileaf collimators (MLCs) are used to create highly contoured dose distributions utilizing various techniques. “Step and shoot” IMRT uses multiple static fields, typically 5 to 9, with specific dose maps entering the patient from multiple beam angles. “Sliding window” IMRT utilizes an arcing motion of the radiation source along with movements of the MLC leaves. Helical Tomotherapy is a variation of the sliding window technique in which the radiation source is constantly moving around a patient and the patient is translated through the path of the beam while the MLCs rapidly open and close to create the desired dose distribution. Recently, the use of volumetric modulated arc radiotherapy using linear accelerators has been adopted into clinical practice as another IMRT technique.

Potential benefits of IMRT include the ability to preferentially limit the dose of radiation to normal tissues, safely deliver higher

FIGURE 21.14. Typical dose distributions using intensity-modulated RT to deliver pelvic RT in cervical cancer.

tumor doses, and enable treatment and retreatment of tumors that are otherwise less amenable to treatment (Fig. 21.14).

Dose-volume histograms (DVHs) plot the percentage of a certain organ or volume of interest versus the dose received (Fig. 21.15). By looking at a DVH, the radiation oncologist can quickly and quantitatively assess whether the dose delivered to critical structures and tumor volumes is adequate for safety and efficacy of treatment. Furthermore, DVH analysis provides an objective method of comparing different treatment plans. The increasing use of IMRT requires a better understanding of radiation dose-volume relationships than has existed in the past. Although consensus regarding proper dose-volume constraints for most normal tissues is not absolute, continued experience has narrowed the disagreement.

Jhingran has published an extensive review of IMRT use in gynecologic malignancies (291). Data support the ability of IMRT to reduce dose to normal tissues and thereby reduce acute and late toxicities. Treatment of recurrences in or near previous RT fields, dose escalation to grossly involved lymph nodes (Fig. 21.16), and treatment of patients with vesico- or rectovaginal fistulae are

also facilitated. There is debate regarding the ability of IMRT techniques to replace ICBT for treatment of cervical cancer (300,301). To date, the weight of opinion does not support this latter indication (302,303).

Randall and Ibbott have presented a discussion of possible pitfalls and hazards from implementation of IMRT for gynecologic cancers (304). Chief among these concerns is the problem of organ and tissue motion. In addition to respiratory motion, in the pelvis there is considerable motion with varying amounts of distension of the bladder and rectum (305) (Fig. 21.17). In addition, patient and tumor geometry often change during treatment. Beadle et al. evaluated the magnitude of cervix regression and motion during external beam chemoradiotherapy. They demonstrated that cervix regression contributes to marked interfraction variations in the intrapelvic position of the cervical target (306). These geometric uncertainties could require substantial margins around CTVs. As a result, it was felt that the potential value of IMRT was diminished and the risk of missing tumor was increased. To overcome the problem, various adaptive strategies to decrease PTV margins are now under investigation (307,308).

FIGURE 21.15. This dose-volume histogram (DVH) compares a 4-field “box” arrangement (*squares*) with an IMRT plan (*triangles*). The DVH plots doses to the planning target volume (PTV) and the organs at risk (OARs).

FIGURE 21.16. Intensity-modulated radiation therapy (IMRT) used to treat a pelvic node recurrence after RH.

For proper delivery of IMRT, accurate and reproducible target volume definition is essential in order to minimize the risk of a geographical miss with the tightly conformal fields often used. To minimize the risk of variation for target volume delineations, guidelines have been published. Taylor et al. have presented guidelines for contouring CTV of pelvic lymph nodes for patients undergoing RT, suggesting that a 7-mm margin around iliac vessels presents a reasonable trade-off in terms of maximizing nodal coverage while limiting small bowel dose (309). Consensus guidelines for both pelvic node CTV (310,311) and primary tumor CTV (312,313) have been published by the Gyn IMRT Consortium and the Japan Clinical Oncology Group (Fig. 21.18). In the case of the Gyn IMRT Consortium, an MRI scan was used to create the volumes, in contrast to how treatment planning is most commonly done. Although substantial agreement was seen for the GTV definition, only moderate agreement was seen for volume definitions of cervix, uterus, vagina, and parametrium.

Other concerns with IMRT include an increase in the incidence of secondary radiation-induced malignancies (314,315), limitations of imaging in accurately defining pelvic disease, increased dose heterogeneity, and problems with quality assurance (304). In addition there are concerns regarding deleterious effects of prolonged treatment times on the radiation-induced cell killing (316). Finally, many technical issues are of concern, including the fact that dose distributions are less reproducible and the fact that calculated dosimetry might not reflect what is actually delivered to the patient for many reasons (317). Despite these issues, clinical outcomes of patients with cervical cancer treated with IMRT have been published, especially in

FIGURE 21.18. Contouring of primary tumor CTV (yellow), nodal CTV (orange), and PTV (red) for cervical cancer. PTV is created with 0.5 to 1.5 cm margins for CTV primary and 0.5 cm for CTV node in this case.

the postoperative setting. Promising results have been reported (318–320).

Extended Field RT

The reluctance among some radiation oncologists to utilize extended field radiation therapy (EFRT) either prophylactically or therapeutically in some cases relates to concern over increased acute and late toxicities. This is largely because the paraaortic chain is surrounded by organs of limited radiation tolerance, that is, spinal cord, kidneys, small intestine. The use of opposed anterior and posterior fields is the easiest technique but may deliver a dose that exceeds tolerance to the small bowel if an appropriate dose for microscopic disease is delivered. Various techniques have been utilized in an effort to deliver EFRT, all of which have advantages and disadvantages. A 4-field technique permits continuity with and use of a 4-field approach in the pelvis, spares much of the small intestine, and shields the spinal cord and the vast majority of the kidneys from half of the beams (Fig. 21.19). It is important to perform an IVP or CT to accurately determine the kidneys' location. The dose to the kidneys can be kept within tolerance by preferentially weighting the anterior and posterior beams (e.g., 70:30 AP-PA to laterals). In most cases, this will be adequate to limit kidney doses within tolerance, even when delivering 40 to 45 Gy to the volume. Nevertheless, it is critical to know the kidney doses and the amount of the renal parenchyma receiving this dose when utilizing this technique. IMRT could offer a more favorable dose distribution than extended field RT.

FIGURE 21.17. (A & B) Sagittal reconstructed images of simulation (A) and cone-beam CT (B). Bowel movement to caudal direction (red arrows) is observed on the cone-beam CT image compared with the simulation CT image. Bladder filling affects the position of the uterine body and the bowel (blue arrows).

Metastatic involvement of the PANL region in cervical cancer is a somewhat unique situation compared to other malignancies. In the TNM staging systems of AJCC and UICC, this region is considered to be an extra-regional area. Therefore when metastatic disease is detected in the paraaortic region, the patient would be staged as M1 in TNM system or IVB in the FIGO staging system (if the paraaortic involvement is detected clinically). For patients with other primary cancers, elective or therapeutic RT to the extra-regional area with curative intent is unlikely to be indicated. In contrast, RT to extra-regional PANL involvement can be curative in cervical cancer.

Elective Paraaortic Lymph Node Irradiation

Data from the GOG suggests that in patients with stages IB, II, III, and IVA cervical cancer, the disease will have spread to the paraaortic lymph nodes in 5%, 16% to 21%, 25% to 31%, and 13%, respectively (8). Therefore occult involvement of the paraaortic lymph nodes is a potential cause of treatment failure in carcinoma of the cervix. Given the orderly lymphatic spread of cervical carcinoma to pelvic and paraaortic lymph nodes and its frequency in defined patient groups, adjuvant EFRT is a logical treatment strategy that seeks to avoid the risks and treatment delays associated with surgical staging. Its use may be considered in patients with early-stage disease who have undergone appropriate surgical treatment and have risk factors arguing for adjuvant postoperative RT, and in patients for whom RT is the primary treatment.

The European Organization for Research and Treatment of Cancer (EORTC) study reported by Haie et al. (321) included 441 patients with stages I–III disease who did not have surgical staging, but were considered at high risk of undetected paraaortic lymph node involvement. In the study group, the paraaortic area was to receive 45 Gy with EBRT. Significant findings included a higher rate of gastrointestinal toxicity, a significantly lower rate of paraaortic failures in the EFRT group, and a significantly lower rate of distant metastases in patients receiving EFRT and achieving pelvic control. There was no statistically significant difference between the 2 treatment arms with regard to local control, distant metastases, DFS at 4 years, or survival. The incidence of small bowel injury was 0.9% in the pelvic RT and 2.3% in the EFRT groups. A severe complication rate of 9% was observed in patients receiving EFRT, compared with 4.8% in those treated to the pelvis only. Rotman et al. published 10-year results from Radiation Therapy Oncology Group (RTOG) study 79–220 (322). In this study, 367 patients

(stage IIB or stages IB–IIA ≥ 4 cm) were randomized to pelvic RT versus EFRT. OS was 67% at 5 years and 55% at 10 years for the patients receiving elective EFRT, compared with 55% and 44%, respectively, for those treated to the pelvis only ($p = 0.02$). Locoregional failures were similar at 10 years for both arms (pelvic only, 35%; EFRT, 31%). When the first disease failure patterns were examined, more patients failed distally when treated only with pelvic RT compared to those receiving EFRT ($p = 0.053$). The EFRT arm was associated with more grade 4 and 5 complications, particularly in patients with prior abdominal surgery (11% vs. 2%).

Results from RTOG 90–01 showed that pelvic RT combined with platinum-based chemotherapy is superior to adjuvant EFRT in patients with locally advanced disease (323). However, given the apparent ability of EFRT to impact failure rates in the paraaortic chain and the improving therapeutic ratio, EFRT combined with chemotherapy could offer opportunities for improved outcomes in patients at high risk of metastatic paraaortic disease. Possible indications for its consideration include positive PET scans in the paraaortic region; high pelvic lymph nodes involved, for example, common iliac; gross nodal metastases in the pelvis; bilateral positive pelvic lymph nodes; adenocarcinoma histology with any number of positive pelvic lymph nodes; and squamous cell histology with 4 or more positive pelvic lymph nodes. In all cases, the radiation oncologist must determine that the patient is in reasonably good general health, with no or limited risk factors for RT injury. Furthermore, there should be an assessment that there is a good chance of pelvic control (in patients receiving primary RT), since the absence of pelvic control will render paraaortic control meaningless.

Therapeutic Paraaortic Lymph Node Irradiation

Based on a retrospective review of 35 patients treated for documented paraaortic lymph node spread, Stryker and Mortel suggested that EFRT can contribute to cure in approximately 30% of these patients (324). Patients with only microscopic involvement had considerably better outcomes than those with gross disease (42% vs. 26% 5-year survival). Grade 4 morbidity was seen in 8.6%, although in all cases the morbidity was related to the pelvic portion of the treatment rather than the EFRT. Grigsby et al. also reviewed 43 patients with cervical cancer who had biopsy-proven positive paraaortic lymph nodes treated with EFRT (325). The 5-year cause-specific survival rate was 49%. They demonstrated that the majority of failures occurred at distant sites. Compared to most studies showing limited toxicity, Small et al. observed very high acute and late toxicities with therapeutic paraaortic RT. Differences in the treatment regimens included the use of weekly cisplatin at 40 mg/m, more frequent boosting of paraaortic nodes, and high dose-rate brachytherapy in the RTOG study (326). A second phase of this study accrued 18 patients with positive paraaortic or high common iliac lymph nodes. In an effort to limit toxicity, these patients received the radioprotector amifostine along with their RT. Acute toxicity was not decreased, nor was late toxicity significantly diminished (327). Walker et al. reported follow-up data of a phase I/II GOG study on EFRT with concurrent paclitaxel and cisplatin chemotherapy in patients with cervical cancer metastatic to the paraaortic nodes (328). Favorable feasibility and an excellent 5-year survival rate of 45% were demonstrated. However, the incidence of severe late toxicity was unexpectedly high. Based on the nature of the complications observed, it was felt that a high central radiation dose was mostly responsible for the complication rate, rather than the utilization of EFRT or concurrent delivery of chemotherapy.

Therapeutic EFRT in patients with paraaortic metastases appears to be efficacious, resulting in long-term survivals of

25% to 50%. Definable subgroups may have an even higher rate of long-term survival. EFRT can reliably control microscopic disease in the paraaortic chain; however, the curability of the individual patient is more a function of the ability to gain control of the pelvic disease and the likelihood that the patient will develop other metastatic disease, although the incorporation of concurrent chemotherapy into standard management of these patients may decrease systemic failure. Furthermore, the use of “outback” chemotherapy following definitive chemo-RT is under active investigation as a strategy to further decrease systemic failure.

Particle Beam Radiotherapy

There is increasing interest in and availability of proton beam RT, although the reported experience in cervical cancer is limited. Kagei et al. reported 25 patients, stages IIB-IVA, treated with curative intent by photon pelvic RT followed by a proton boost to the primary tumor. No intracavitary RT was given. Long-term survival and complication rates were considered similar to those of conventional photon RT plus ICBT (329). Recently, several techniques for administration of proton RT have been presented to potentially achieve a higher therapeutic ratio. Milby et al. demonstrated that a combination of passive scattering proton therapy (PSPT) + IMRT and intensity-modulated proton therapy (IMPT) + IMRT had a statistically significant dose reduction to the small and large bowel and kidneys compared with IMRT alone, while maintaining excellent PTV coverage (330). Carbon ion RT has some biologic advantages over photons and protons, including a decreased oxygen enhancement ratio. Kato et al. reported a dose escalation study of carbon ion RT for locally advanced carcinoma of the cervix. A promising 5-year local control rate of 69% for stage IVA patients was demonstrated, but 8 out of 44 patients developed major late gastrointestinal complications (331).

Brachytherapy

Brachytherapy refers to the placement of radioactive sources at a short distance from the intended target. Because the anatomy of cervical cancer typically facilitates brachytherapy, and because brachytherapy permits very high doses to be safely delivered, it has long been a major factor in the ability of RT to cure cervical cancer. Several isotopes are available for cervical cancer brachytherapy, although at the present time ^{137}Cs is the most popular for low-dose-rate (LDR) brachytherapy. ^{192}Ir is frequently used for high-dose-rate (HDR) brachytherapy because of its high specific activity. It is also frequently used at lower activities for removable LDR interstitial applications. Brachytherapy can be delivered with intracavitary techniques using applicators typically consisting of an intrauterine tandem and vaginal colpostats or, when necessary, vaginal cylinders. All state-of-the-art applicators are afterloading. Interstitial implants are typically done with removable isotopes such as ^{192}Ir , although there is a role for implants with permanent isotopes, for example, Au-198, Cs-131, especially in small volume vaginal recurrences. Recently, the American Brachytherapy Society provided updated recommendations for brachytherapy for locally advanced cervical cancer (332,333).

Intracavitary Implants

ICBT is generally used in combination with external beam RT, although it may be used alone in very early disease. LDR has been used since the early 1900s, but since its inception the late 1950s with the Cathetron Cobalt-60, HDR brachytherapy has become increasingly utilized (292,334).

Three brachytherapy systems were developed almost simultaneously: the Paris, Stockholm, and Manchester systems. The term

“system” denotes a set of established rules, taking into account the source strength and the geometry, method, and duration of the application in order to obtain suitable dose distributions. In each of these systems, a brachytherapy insertion consisted of an intrauterine component (tandem) and a vaginal applicator. Treatment duration and loadings were developed empirically. Intracavitary treatment prescriptions could be quantified in terms of milligram-hours, that is, the product of the total mass of radium or radium equivalent (e.g., ^{137}Cs) contained in the sources, and the duration of the application in hours.

The classical Manchester system was the first system to use units of radiation exposure (Roentgens) rather than milligram-hours to prescribe dose. The dose (in Roentgens) was prescribed at specific points, termed A and B. Point A was originally defined as a point 2 cm lateral to the center of the uterine canal and 2 cm from the mucous membrane of the lateral fornix in the plane of the uterus. Point A was intended to represent the average dose to the “paracervical triangle.” Point B was defined as 5 cm from the patient’s midline at the same level as point A, and it was intended to quantify the dose received by the regional (obturator) lymph nodes. The various combinations of Manchester system ovoid dimensions and applicator loadings were designed to provide a reasonably constant point A dose rate of 50 to 55 cGy/hour. This approach heavily influenced intracavitary treatment practice patterns in the United States. The widely used Fletcher-Suit applicator system, Fletcher loadings, and the reference points A and B are all derived from this system.

Computer-generated isodose curves provide the best means of determining the doses to point A, point B, bladder, and rectum (Fig. 21.20 A and B). International Commission on Radiation Units and Measurements (ICRU) Report No. 38 (335) defines the dose and volume specifications for reporting intracavitary therapy in gynecologic procedures. ICRU-38 recommended that reference points such as point A not be used, because “such points are located in a region where the dose gradient is high and any inaccuracy in the determination of the distance results in large uncertainties in the absorbed doses evaluated at those points.” Instead, it introduced the concept of reference volume, that is, the tissue volume encompassed by a reference isodose surface, recommending that the dimensions of the 60-Gy isodose surface be specified, including the contribution of EBRT. They proposed that this pear-shaped reference volume be described in terms of its 3 dimensions: height (maximum dimension along the intrauterine sources), width (maximum dimension perpendicular to the intrauterine sources), and thickness (maximum dimension perpendicular to the intrauterine sources in the oblique sagittal plane), measured in the oblique, coronal, and sagittal planes containing the intracavitary sources. Weaknesses of the ICRU-38 recommendations have been pointed out, including the absence of rationale for the choice of 60 Gy. Widespread adoption is, therefore, lacking (336). However, the ICRU definitions of rectal and bladder points are frequently used. Dose prescription at point A is still widely used in clinical practice (337). Point B dose calculation could be optional, because data from 3-D planned brachytherapy revealed point B dose could not be a surrogate for dose to specific nodal group (338).

If the vaginal vault is narrow, making it impossible to insert regular colpostats, miniovoids can be used (usually loaded with 10 mg RaEq sources for LDR implants). When miniovoids cannot be inserted, an option is to use a protruding source in the vaginal vault, which is inserted in the afterloading tandem (usually 20 to 30 mg RaEq) with an overlying plastic sleeve (Delclos ring). Afterloaded vaginal cylinders are used in conjunction with an intrauterine tandem to irradiate the vagina when the disease extends from the uterine cervix along the vaginal walls. Cylinders are available in various diameters (1 to 5 cm) and lengths to fit any vaginal width and length (Fig. 21.11).

For LDR implants, the first intracavitary insertion is generally scheduled after 40 to 45 Gy of EBRT, in order to decrease

FIGURE 21.21. Image-guided brachytherapy (IGBT) for cervical cancer using CT images. Table (lower right) shows DVH data.

The ICRU defines LDR as exposures between 40 and 200 cGy/hour, medium dose rate (MDR) as between 200 and 1,200 cGy/hour, and HDR as >1,200 cGy/hour (100). All agree that clinically significant differences exist between LDR, MDR, and HDR. In general, as the dose rate is lowered, the biologic effect of the radiation is decreased owing to the ability of tissues to repair sublethal radiation damage and to repopulate. While there is probably no inherent difference in these parameters between tumor and normal tissues, there is apparently a substantial difference when one considers acute-responding (rapidly proliferating) versus late-responding (slowly proliferating) tissues. Late-responding tissues have a greater capability for repair than tumor or early-responding tissues, but this repair does not take place as fully with high dose rates. Therein lies the radiobiologic dilemma: higher dose rate or large doses per fraction cause relatively more severe late damage than tumor cell kill during HDR brachytherapy or external beam therapy.

To a large degree, published data documenting the effectiveness of RT has been obtained with continuous LDR intracavitary techniques, which have been used for nearly a century. However, even within the dose-rate range considered LDR (0 to 200 cGy/hour), a strong dose-rate effect is likely (347,348). Using a slightly higher dose rate (in the low MDR range), Patel et al. suggested, based on analysis of their clinical experience, that a dose reduction factor of approximately 30%, in comparison to a typical LDR range of 50 to 55 cGy/hour, would be required when using a dose rate of 220 cGy/hour at point A (349).

Pulsed LDR brachytherapy has also been investigated as a possible means of preserving the radiobiologic advantages of LDR while taking advantage of dose optimization offered by HDR technology. Swift et al. reported their experience in 65 patients, 42 of whom had cervical cancer (350). Median follow-up was only 15 months. In these patients with cervical cancer, 23 were alive without known disease at the time of the report. The 2-year actuarial survival rate was 65%, and the 2-year actuarial incidence of late complications was 14%. The authors concluded that pulsed LDR was feasible and produced good local control rates. Bachtiary et al. compared outcomes of patients treated with LDR (109 patients) and pulsed dose rate (PDR)

(57 patients). Seventy patients also received concurrent cisplatin. No significant differences were noted in outcomes or toxicities (351). Recently, the ABS published consensus guidelines regarding application of LDR and PDR brachytherapy for cervical cancer (352).

The use of HDR in the curative management of cervical cancer is becoming more accepted, presumably because the outpatient treatment may be more convenient, afterloading LDR machines are no longer manufactured, and Cs-137 sources are difficult to replace as they decay. Other suggested advantages of HDR implants include better stability of the implant and source positions during the short duration of the implant and better ability to optimize dose distributions. The literature reflects considerable inconsistency in terms of whether complication rates are increased with HDR over LDR. Although many retrospective series and a few randomized trials have been reported, results are difficult to interpret. Hareyama et al. published a randomized trial of 132 patients with stage II or IIIB disease (353). External RT doses were identical, and a conversion factor of 0.588 was used to convert LDR to HDR. The 5-year disease-specific survival rates were 69% and 51% with HDR in stages II and III, respectively. This compared with 87% and 60% with LDR. Pelvic recurrence-free survival with HDR was 89% and 73% for stages II and III, versus 100% and 70%, respectively, in the LDR group. Actuarial complication rates ($\geq$ grade 3) at 5 years were 10% with HDR and 13% with LDR. These differences did not reach statistical significance, although stage II patients treated with LDR had a better survival rate than those treated with HDR.

Ferrigno et al. published a retrospective series of 190 patients treated with LDR from 1989 to 1995 and 118 patients treated with HDR from 1994 to 2001. With median follow-ups of 70 and 33 months in the LDR and HDR groups, respectively, no significant differences were seen in OS, DFS, and local control among stage I-II patients. However, for stage III patients, OS and DFS were significantly better in the LDR group, and local control was also better, although not at a statistically significant level (354). Falkenberg et al. reported a single institution study comparing outcomes of 103 patients treated with LDR versus

FIGURE 21.22. A and B: High-dose-rate interstitial brachytherapy for vaginal stump recurrence. **A:** External view of the application. Vinyl template applicators are used in this case. **B:** Dose distribution curves superimposed on a relevant CT image. Red line: 100% prescribed isodose line. Orange line: CTV (Special courtesy of Dr. K. Yoshida, Department of Radiology, Osaka National Hospital).

57 patients treated with HDR. No significant differences were seen in any stage in this series (355). Stewart and Viswanathan nicely reviewed current controversies in the dose rate issues (356). They acknowledged are challenges in using HDR for patients with stage III disease who exhibit poor response to EBRT.

To facilitate multiple insertions, intrauterine stents can be used so that applicators can be placed quickly, without cervical dilatation, using little or no sedation. In some institutions, treatment planning is performed on the initial insertion and is duplicated for all subsequent fractions by verifying the applicator position with fluoroscopy or radiographs. In the event that specifics of the implant change (e.g., tandem length), treatment planning must be redone to account for the change. In addition to fractionation, clinical experience has demonstrated that some method of increasing the distance from the HDR sources to the rectal wall is mandatory to keep rectal doses and subsequent sequelae at acceptable levels. Various techniques, including rectal retractors, vaginal speculums, gauze packing, and intravaginal Foley catheter balloons, are used to achieve this goal. Technical details for HDR application are described in the ABS guidelines (337,338).

Interstitial Implants

Interstitial implants are an option when intracavitary implants are impossible. Implants are typically planned and facilitated using perineal templates such as the Syed-Neblett Interstitial Template (Fig. 21.22). The use of endorectal MR coils and transrectal ultrasound can facilitate needle placement by improving visualization of tumor and normal tissues in relation to needle position. In some cases, this is done in conjunction with open laparotomy or laparoscopy. Image-guided interstitial implants with MRI could be a promising alternative for patients whose tumors are considered difficult to cover by conventional ICBT (357). Combined intracavitary/interstitial brachytherapy has also been described as technically feasible for these patients. Promising treatment outcomes have been reported (358).

Patients are typically selected for interstitial therapy on the basis of practical difficulties that preclude intracavitary therapy;

thus, they may not be comparable to patients treated in a more conventional manner. However, until further improvements and better data supporting the efficiency and safety of this technique are available, its use in locally advanced cervical cancer should be only in exceptional circumstances, and by experienced brachytherapists. Furthermore, IMRT is likely to prove to be an effective alternative to interstitial therapy in patients who are not candidates for intracavitary therapy. However one should keep in mind that there are some unresolved issues with regard to delivering appropriate IMRT for intact cervical cancers, as mentioned above (304).

Doses of Irradiation

When RT is used as curative intent treatment for primary cervical cancer, radiation dose will almost always be quite heterogeneous due to the need to deliver much higher doses to the cervical mass and its gross extensions (GTV) and grossly involved regional lymph nodes as compared to elective treatment of clinically uninvolved regional nodes. Typically, this dose gradient is created with a combination of external beam pelvic RT with intracavitary therapy, used to escalate the dose to the primary tumor. Some institutions use lower doses of pelvic RT (e.g., 20 to 36 Gy with the addition of parametrial doses to complete external beam therapy utilizing a MLS. Many institutions in the US prefer higher doses of pelvic external irradiation (usually 40 to 45 Gy), delivered by 4-field box or IMRT technique. If utilizing LDR brachytherapy techniques, approximately 40 to 55 Gy to point A is added with 1 or 2 LDR intracavitary insertions, depending on tumor stage, volume, and doses delivered to critical structures. Usual doses to point A from both the external irradiation to the pelvis and the LDR intracavitary brachytherapy can range from 70 Gy for small (≤ 1 cm) stage IB tumors to 90 to 95 Gy for stage IIB or IIIB tumors, if normal tissue doses permit. An additional parametrial boost is administered in some patients with IIB, III, or IVA tumors (factoring in the dose delivered to the sidewall by the brachytherapy component). In patients with only unilateral parametrial involvement, consideration should be given to boosting only the involved side.

Table 21.5 Suggested Schedules of HDR-ICBT in the United States

EBRT	HDR-ICBT (Point A)	EQD2 (Point A)
45 Gy/25 fx	7 Gy × 4	83.9 Gy
	6 Gy × 5	84.3 Gy
	5.5 Gy × 6	79.8 Gy
	5 Gy × 6	81.8 Gy

Note: For tandem and ovoid or tandem and ring applicators.

HDR-ICBT, high dose-rate intracavitary brachytherapy; EBRT, external beam radiotherapy; EQD2, normalized therapy dose.

When using HDR brachytherapy, it is necessary to use multiple HDR fractions and to decrease, as much as possible, the dose to late-responding tissues to decrease the likelihood of increased late effects. Peterit and Pearcey (359) used 45 Gy/25 fractions of external beam irradiation to the pelvis, combined with 5 HDR fractions (5.5 to 6 Gy per fraction), or 4 fractions of HDR brachytherapy (6.5 to 7 Gy in each fraction). The equivalent LDR brachytherapy at point A is 80 Gy, with 67 Gy delivered to the bladder or the rectum, assuming that these tissues receive 70% of the prescribed point A dose. Table 21.5 shows examples of regimens popularly used in the US for tandem and ovoid or ring applicator brachytherapy presented by ABS (333).

Clinical outcomes of patients treated with the US schedules have been reported. Anker et al. retrospectively evaluated local control and toxicity of 65 cervical cancer patients who received external beam RT and HDR (360). With a median BED at point A of 101 Gy₁₀ (EQD2 = 84 Gy), excellent 3-year local control of 97% was reported. On the other hand, actuarial 3-year Grade 3 or greater toxicity was 17%. Almost all patients received concurrent chemotherapy. Forrest et al. (361) presented an analysis of patients who received pelvic radiotherapy of 45 Gy with parametrial boosts of 5.4 or 9 Gy and HDR of 30 Gy in 5 fractions to point A (EQD2 = 85 Gy), which was a former standard radiotherapy schedule of the GOG. Although pelvic control was favorable (overall pelvic failure rate of 14%), the actuarial grade 3/4 toxic effect rate at 2 years was 14%.

Based on a perceived and observed escalation in complication rates compared to the LDR techniques used in earlier clinical trials, the GOG amended the standard HDR brachytherapy prescription to deliver a pelvic dose of 41.4 to 45 Gy to be followed by an HDR prescription dose of 5.3 to 6 Gy for 5 fractions for a total dose of 70 to 75 Gy.

Favorable local control outcomes with low levels of late toxicity were reported in Japanese prospective multi-institutional studies of definitive RT with lower doses of HDR brachytherapy compared to the doses typically used in the United States (295). Whether this observation can be explained by anatomic variation, different tumor biology, or other reasons is not clear at this time. More clinical data with DVH parameters of IGBT, close observation, and extended follow-up are needed to establish optimum brachytherapy treatment schedules using HDR brachytherapy.

Altered Fractionation

Conventional RT schedules typically employ fraction sizes of 180 to 200 cGy, given 5 days per week over a number of weeks. Altered fractionation refers to the use of nonstandard dose and fractionation schedules. Radiobiologic research and modeling suggest that these different fractionation schedules could favorably impact control rates, complication rates, or both. Examples include hypofractionation (larger doses per fraction, lower total dose), hyperfractionation (smaller doses per fraction given more

frequently, e.g., 2 to 3 fractions per day, to a slightly higher total dose), accelerated fractionation (standard fraction sizes given more frequently, e.g., twice daily), and concomitant boost techniques (a larger volume is treated in standard fashion, while part of the volume, typically gross tumor, is treated with an additional smaller fraction on the same day, separated by 4 to 6 hours). The development of IMRT techniques, described earlier, has made it possible to create dose gradients to escalate dose to gross disease, for example, enlarged lymph nodes, while maintaining standard fractionation to areas of potential microscopic disease, a form of concomitant boost.

Ohno et al. reported the toxicity and outcomes of an accelerated hyperfractionated RT for locally advanced cervical cancer (362). They conducted a multi-institutional prospective study among 8 Asian countries. Protocol treatment consisted of whole pelvis RT of 30 Gy, 1.5 Gy/fraction twice daily, followed by 20 Gy of pelvic RT with central shielding at a dose of 2-Gy fractions daily and HDR of 18 to 20 Gy/3 to 4 fractions or LDR of 45 to 60 Gy/2 fractions. The median overall treatment time was 35 days. The 5-year pelvic control and OS rate for all patients were 84% and 70%, respectively. The 5-year actuarial rate of Grade 3 to 4 late toxicity at any site was 5%. This treatment strategy could be a treatment option, for example, in patients who cannot receive CCRT.

Overall Treatment Time

Owing to the radiobiologic phenomena of tumor cell repopulation and accelerated repopulation, clinicians have long assumed that treatment prolongation, beyond some reasonable point, would have a deleterious effect on outcome in patients treated with RT. Several studies have supported this assumption by demonstrating lower pelvic tumor control and survival rates after definitive RT in invasive carcinoma of the cervix when the overall treatment time is prolonged.

Combining the published results, largely from the prechemoRT era, one can suggest that pelvic control will suffer at an approximate rate of 1% per day that treatment extends beyond 52 to 55 days. This impact will be potentially seen in all stages of localized disease, and survival will be negatively affected. Erridge et al. have pointed out that there is probably a limit to the relationship between treatment time and outcome (363). In a cohort of patients, almost all of whom completed treatment within 7 weeks, no impact of overall treatment time was observed. However, grade 4 toxicities were more common among patients completing treatment on a compact schedule of 29 to 32 days.

Monk et al. suggested that prolonged overall treatment times negatively impact outcomes for patients with locally advanced cervical carcinoma treated with weekly cisplatin and pelvic RT (364). They reviewed data from 335 women who participated in GOG studies and demonstrated that a prolonged course of RT was associated with poorer PFS and OS.

Feddock et al. reviewed curative intent treatment of 227 patients with cervical cancer, separating them into 2 groups based on overall treatment time of less than 8 weeks versus ≥8 weeks. With a median follow-up of 38 months, there was a decrement in cause-specific survival with prolonged treatment time in patients managed with LDR brachytherapy. However, a similar decrement was not observed in patients managed with HDR brachytherapy (365).

Palliative or Emergent Irradiation

The radiation or gynecologic oncologist is often faced with treating a patient who requires palliation of pelvic pain, obstruction, or bleeding. If vaginal bleeding is the main concern, bleeding can be controlled by vaginal packing, followed by the immediate institution of EBRT. It can be appropriate, particularly in

noncurative situations such as metastatic disease, to treat a slightly smaller pelvic volume. Doses per fraction slightly higher than standard, for example, 250 to 300 cGy will more quickly result in hemostasis while still allowing patients with localized disease to be approached with curative intent, without an excessive risk of complications. As an alternative strategy, a single intracavitary implant with tandem and colpostats can be used. Again, this does not preclude curative intent treatment for patients with localized disease.

Patients with stage IVB or incurable recurrent carcinoma often require palliation of pelvic pain or bleeding, and their general condition may not warrant a prolonged course of external irradiation. Spanos et al. (366) reported an RTOG phase 3 study of accelerated split-course palliative irradiation in 284 patients. Patients received 3 courses of 14.8 Gy in 4 fractions over 2 days, with a rest of 2 to 4 weeks between courses, up to 44.4 Gy total dose. There were 136 patients randomized to rest periods of 2 or 4 weeks. There was a trend toward increased acute toxicity in patients with shorter rest periods (5 of 68, versus 0 of 68; $p = 0.07$). Late toxicity was not significantly different in the 2 groups, although length of follow-up was not sufficient to accurately assess it. Pelvic tumor response was comparable in both. More patients in the 2-week rest period group completed the 3 courses of therapy, but the most significant predictor for completion of therapy was Karnofsky performance status of 80 or higher. This schedule offers significant logistic benefits and has been shown to result in good tumor regression and excellent palliation of symptoms.

CHEMOTHERAPY

Chemotherapy is an integral part of the multidisciplinary approach to the treatment of cervical cancer. While chemotherapy is most often given concurrently with radiation in the setting of locally advanced disease, it is also administered in the neoadjuvant setting prior to surgery or radiation and in the recurrent and metastatic disease setting as palliative therapy (367). When administered concurrently with radiation, the most commonly used chemotherapeutic agent is single agent cisplatin, though other agents used alone or in various combinations include capecitabine, carboplatin, epirubicin, 5-fluorouracil, hydroxyurea, irinotecan, mitomycin, nedaplatin, topotecan, and vinorelbine (367,368). In the neoadjuvant, recurrent, or metastatic settings, capecitabine, carboplatin, cisplatin, epirubicin, gemcitabine, ifosfamide, irinotecan, paclitaxel, pegylated liposomal doxorubicin, topotecan, and vinorelbine are used as single agents or in various combinations. More recently, biologic agents such as bevacizumab and cetuximab and hypoxic cell sensitizers such as tirapazamine are being used as single agents or in combination with chemotherapy in the treatment of cervix cancer (367,368).

COMBINED MODALITY TREATMENT

Adjuvant Hysterectomy after Radiation Therapy

Multiple retrospective series have been reported comparing preoperative RT plus adjuvant hysterectomy postradiation therapy (AHPRT) with curative intent RT or chemo-RT without AHPRT. Most commonly, no improvement in tumor control or survival is noted, although other series report improved pelvic control rates and possibly improved survival. Given the retrospective nature of these series, the authors acknowledge likely biases in patient selection, limiting the ability to draw conclusions.

A randomized trial to address this question was performed by the GOG. Keys et al. reported 256 patients with cervical cancers greater than 4 cm in size who were randomized to curative doses of pelvic RT with brachytherapy versus preoperative doses of RT and brachytherapy plus AHPRT. The relapse rate was significantly lower in the AHPRT arm versus RT alone (27% vs. 14%). The incidence of progression was somewhat higher in the RT alone group at 46% versus 37% ($p = 0.07$) in the AHPRT group. However, no OS advantage was seen, and the toxicities were similar in both groups. Pathologic evaluation of hysterectomy specimens revealed 48% with no residual disease, 40% with microscopic disease, and 12% with grossly positive tumor. Patients with grossly positive tumors had a death rate seven times higher than those with negative specimens (179).

The main impetus for AHPRT is to decrease the incidence of pelvic recurrence; however, its use remains controversial because OS appears to be unaffected. Patients who could potentially benefit include those with bulky endocervical lesions greater than 4 cm in size and patients with difficult anatomy that limits appropriate placement of brachytherapy applicators. Patients with persistent disease after RT may benefit from planned hysterectomy.

Adjuvant Postoperative Pelvic RT

The most common failure pattern following radical surgery for cervical carcinoma is pelvic relapse. Based on an extensive GOG clinico-pathologic study, Delgado et al. proposed separate intermediate- and high-risk groups as well as a “GOG score” (171). These risk group definitions have become generally accepted and incorporated into the design of both prospective trials and retrospective reports. Intermediate-risk criteria relate to tumor size, depth of stromal invasion, and LVSI; these are presented in Table 21.6. High-risk criteria include positive pelvic nodes, close or positive margins, and parametrial extension. Retrospective and prospective data suggest that adjuvant pelvic RT significantly improves pelvic control rates and DFS in patients with risk factors for recurrence who have completed radical surgery. The role of chemotherapy, particularly in high-risk patients, has also become established.

Intermediate Risk, Node Negative

The GOG conducted a phase 3 trial comparing RH alone with RH and postoperative pelvic RT in patients with node-negative stage IB cervical carcinomas, with prognostic features correlated with an intermediate risk of recurrence (GOG 92) (369). Eligibility criteria for this study are given in Table 21.6. There were 277 patients randomized after RH: 137 to pelvic RT, and 140 to no further therapy. RT consisted of 46 to 50.4 Gy to a whole pelvic field. No brachytherapy was used.

The RT arm had a 46% reduction in the risk of recurrence compared to the observation arm ($p = 0.007$) and a reduction in the risk of progression or death ($p = 0.009$). Particularly striking was the impact of postoperative RT in patients with adenocarcinoma or adenosquamous histologies: among this subset, only

Table 21.6 GOG 92 Eligibility Criteria

Capillary Lymphatic Space Involvement	Stromal Invasion	Tumor Size
Positive	Deep 1/3	Any
Positive	Middle 1/3	≥2 cm
Positive	Superficial 1/3	≥5 cm
Negative	Deep or middle 1/3	≥4 cm

8.8% recurred in the RT arm, versus 44% in the observation arm. There was a strong trend toward improved survival in the RT arm, but this did not reach statistical significance ($p = 0.074$).

Several reasons have been suggested for the inability of this study to conclusively demonstrate a survival benefit in the presence of such a strong impact on recurrence rate. For example, a number of patients randomized to the RT arm did not receive RT and additional patients had protracted treatment or inadequate doses. However, the strongest factor is probably that the study was powered for its primary end point, which was disease-free interval, and was not sufficiently powered to demonstrate a survival benefit.

A retrospective series from the Netherlands looked at 51 patients with intermediate-risk, node-negative tumors. Of these, 34 received RT and 17 did not. The 5-year DFS was 86% in the group receiving RT, compared to 57% in the observation group (370). Ryu et al. retrospectively reviewed treatment outcomes of 172 cervical cancer patients with intermediate risk factors (371). A statistically significant difference was observed in 3-year recurrence-free survival rate among the no adjuvant treatment, postoperative RT, and postoperative CCRT groups (67.5%, 90.5%, and 97.5%, respectively; $p < 0.05$). A prospective trial to investigate whether postoperative CCRT improves survival of intermediate-risk patients compared with RT alone is now underway (GOG 263).

As mentioned previously, Yeo and colleagues used the Delgado GOG score (171) to tailor adjuvant RT in node-negative stage IB-IIA cervical carcinomas. Patients with GOG scores less than 40 were observed, while patients with scores of 40 to 120 and greater than 120 received small-field RT and standard pelvic RT, respectively. The 5-year DFS was 98.2%, and no grade 3 to 4 toxicities were observed (299).

Management of patients with stage IB2 tumors is somewhat controversial, in that some favor initial surgery followed by adjuvant chemo-RT, while others recommend curative intent chemo-RT, avoiding the use of 2 local modalities. This topic is discussed earlier in the chapter.

Node-Positive/High-Risk Patients

Metastatic disease in the pelvic lymph nodes is a poor prognostic sign, as this is associated with a higher risk of both local and distant recurrence. Pelvic nodal metastases may be associated with lesion size, deep stromal invasion, and involvement of capillary or lymphatic vascular spaces. Postoperative RT has been advocated for patients with pelvic nodal metastases, although results vary in different series. A practice-changing intergroup study was conducted by the Southwest Oncology Group (SWOG), GOG, and RTOG in women with FIGO stages IA2, IB, or IIA carcinoma of the cervix found to have metastatic disease in the pelvic lymph nodes, positive parametrial involvement, or positive surgical margins at time of primary RH, and total pelvic lymphadenectomy with confirmed negative paraaortic lymph nodes (142). One hundred twenty-seven patients were randomized between pelvic external beam radiation therapy with 5-FU infusion and cisplatin, and 116 were treated with pelvic external beam irradiation alone. The median follow-up for survivors was 43 months. The 3-year survival on the adjuvant cisplatin/5-FU and irradiation arm was 87%, compared with 77% on the pelvic irradiation arm. The difference is statistically significant. Chemotherapy appeared to reduce both pelvic and extrapelvic recurrences. Acute toxicities were more common in the chemo-therapy arm.

Largely as a result of this study, adjuvant chemo-RT is a standard treatment for these patients. It should be noted that, in this study, a combination of cisplatin 70 mg per m^2 and a 96-hour infusion of fluorouracil 1,000 mg per m^2 for 4 cycles were administered with the RT, which is different from the more commonly used chemotherapy regimen weekly 40 mg per m^2

cisplatin for 5 to 6 weeks. Additional long-term follow-up data are needed regarding late complications with this regimen.

Monk et al. reviewed the data from this randomized intergroup trial to assess the benefit of adjuvant therapies in definable subgroups of patients and to better understand histologic and clinical risk factors for recurrence (143). With a median follow-up of 5.2 years, the survival rates were 80% and 66% for the chemo-RT and RT alone groups, respectively. In a univariate analysis, the benefit of chemotherapy was not significant in patients with tumor ≤ 2 cm and 1 nodal metastasis. Although retrospective, a large and well-analyzed series of patients receiving postoperative RT was presented by Kim et al. (372). Death and recurrence rates increased with the number of positive lymph nodes. Five-year DFS was 89% if no nodes were positive, decreasing to 85%, 74%, and 56% in patients with 1, 2, 3, and 4 or more positive nodes, respectively. Similar data were reported by Uno et al. (373).

Close or Positive Margins/Parametrial Involvement

Eighty-five percent of patients accrued on the SWOG/GOG/RTOG Intergroup study were eligible based on pelvic node involvement. Only 5% of patients accrued to this intergroup study had positive margins, probably because of the reluctance of clinicians to put these patients on a trial that did not allow brachytherapy boosts. Nevertheless, patients with positive or close margins and/or parametrial involvement are also considered to be at high risk and, based on this randomized trial, should be considered for adjuvant chemoradiation. Other data might suggest that some patients, particularly close or positive margin patients, might be adequately treated with only postoperative RT.

Espace et al. retrospectively analyzed 51 patients with close vaginal surgical margins following RH (defined as ≤ 5 mm) (374). Twenty-three patients with negative nodes and close vaginal margins were studied. Although the 16 patients receiving RT had a preponderance of other risk factors, recurrence rates (12.5% vs. 85.7%) and 5-year survival rates (81.3% vs. 28.6%) significantly favored the group receiving adjuvant pelvic RT.

Kim et al. (375) described results for 38 patients receiving postoperative RT after RH for close surgical margins and/or metastatic pelvic lymph nodes. Patients with close surgical margins were treated with intracavitary vaginal ovoid insertions. Patients with positive margins fell into 2 groups: those with positive parametrial margins and those with involved vaginal margins. All 5 patients with involved parametrial margins treated with only cuff brachytherapy suffered local failures, compared with no pelvic failure in similarly treated patients with only vaginal margins positive for tumor.

Uno et al. analyzed 117 patients with parametrial invasion who had undergone radical surgery and received adjuvant RT. Of 51 node-negative patients, only 6 developed extrapelvic recurrence, and the 5-year OS and recurrence-free survivals were 89% and 83%, respectively. Patients with positive nodes fared much worse (373). Similarly, Kodama et al. found excellent outcomes among parametrium-positive patients who were treated with RH and adjuvant RT if lymph node metastasis and vaginal invasion were not present (approximately 90% 5-year survival) (108).

Radiation Therapy Dose and Technique

Vaginal intracavitary RT alone can be appropriate for patients with carcinoma *in situ* with minimally invasive carcinoma at the vaginal margin of resection as the only risk factor. Outpatient HDR brachytherapy is commonly employed because it prevents the prolonged immobilization required for LDR brachytherapy. A commonly utilized treatment regimen consists of 7 Gy per fraction prescribed at 0.5 cm depth; 3 weekly fractions are typically given. The upper 3 to 5 cm of the vagina should be targeted.

ABS recently developed consensus guidelines for adjuvant vaginal brachytherapy (376). Details of technical recommendation are described in the guidelines.

When external RT is used, patients generally should not receive more than 45 Gy to the whole pelvis. Doses up to 50.4 Gy are acceptable when treating fields that limit the amount of small bowel treated, whether this is done by using smaller fields or by IMRT techniques. Brachytherapy or small-field external beam boosts can be given, within tolerance, to increase dose to the central pelvis. The impact of concurrent chemotherapy on complication rates appears to be limited.

The use of IMRT with chemotherapy has been reported to maintain excellent pelvic control rates, with better acute tolerance and fewer chronic toxicities compared to conventional 4-field box RT (377).

CHEMOTHERAPY IN COMBINATIONS FOR LOCALIZED CARCINOMA OF THE CERVIX

Neoadjuvant Chemotherapy Followed by Radiotherapy

While surgery and radiation therapy are the primary treatment options for early-stage cervical cancer, NACT followed by radiotherapy has largely been abandoned in favor of concurrent chemoradiation for locally advanced cervical cancer (378–380). Concurrent chemoradiation therapy is supported by the results of 5 randomized clinical trials prompting the US National Cancer Institute's Clinical Alert in 1999, the long-term follow-up of 3 of these trials, and several meta-analyses including one published in 2010 (142,189,190,191,323,381–387). Nevertheless, a meta-analysis was performed on 18 randomized trials with 2,074 women receiving NACT followed by radiation compared to radiation alone (388). The heterogeneity of the various trials was a major drawback to the analysis. When separate analyses of groups of trials were performed, the 5-year survival improved when shorter chemotherapy cycles and higher dose intensity of chemotherapy were used, even though there was no statistically significant difference in survival when all trials were analyzed together (388). Given the lack of data from randomized trials comparing NACT followed by radiation to concurrent chemoradiation, NACT followed by radiation is not recommended in the routine care of women with localized carcinoma of the cervix outside of participation in a clinical trial.

Neoadjuvant Chemotherapy Followed by Surgery

Surgery and radiation therapy are the treatment options for early-stage cervical cancer and concurrent chemoradiation is the standard of care for locally advanced disease (378,379). Nonetheless, adjuvant chemotherapy (NACT) followed by surgery may have a role in this disease. It has been suggested that NACT may reduce tumor volume and decrease micrometastatic disease, improving resectability and survival, respectively (378,379). A meta-analysis of 5 trials and 872 patients evaluating NACT followed by surgery revealed a 14% absolute improvement in survival at 5 years when compared with radiotherapy alone (388). These results should be interpreted with caution, as the total number of patients was small and the 5 trials were heterogeneous. This heterogeneity consisted of patients treated with different stages of disease (early-stage versus locally advanced), administered different chemotherapeutic regimens, and given adjuvant pelvic radiotherapy following NACT and surgery (388).

A more recent meta-analysis of 6 trials and 1,072 patients revealed a statistically significant PFS but no statistically significant benefit in OS in patients treated with NACT followed by surgery when compared with patients treated with surgery alone (389). Moreover, many of the patients treated with NACT followed by surgery also received adjuvant radiotherapy.

While it remains unclear if NACT followed by surgery is better than surgery alone, 2 randomized Phase III trials are presently ongoing which will address whether NACT prior to surgery is comparable to chemoradiation in this disease. These trials, sponsored by the European Organization for Research and Treatment of Cancer (EORTC 55994, NCT00039338) and the Tata Memorial Hospital in Mumbai, India (NCT00193739), are comparing the overall and PFS of patients with Stage IB2 to IIB cervical cancer treated with neoadjuvant platinum-based chemotherapy followed by RH versus concurrent cisplatin-based chemoradiation (390,391). If, at surgery, women are found to have risk factors for recurrence, adjuvant radiotherapy or chemoradiotherapy is administered.

At this time, NACT followed by surgery is not recommended in the routine care of women with locally advanced cervical cancer outside of the special circumstances. Such circumstances may include sexually active women with bulky Stage IB–IIB cervical cancer interested in avoiding the long-term complications of radiation and wishing to undergo FSS. These women must have no risk factors for recurrence to avoid adjuvant radiation following NACT and surgery. In addition, NACT followed by surgery is appropriate care for women with locally advanced cervical cancer where radiation facilities are limited or not available.

Preoperative Chemoradiation in Advanced Disease

Concurrent chemoradiation is considered the standard of care for locally advanced cervical cancer (142,189,190,191,323,381–386). With 5-year OS of approximately 70% for women receiving this treatment (189), completion surgery following chemoradiation has been performed with the expectation of improving local control and increasing survival. In support of this concept, women with Stage IB2 tumors were randomized to hysterectomy versus no surgery following primary radiotherapy without chemotherapy (179). Results of this study revealed that adjuvant surgery provided no additional benefit in the 5-year OS of these women though the 5-year recurrence rate in the pelvic region was significantly lower (15% with surgery versus 27% without surgery). In addition, the 5-year OS was statistically significant in subset analyses in women with tumors less than 7 cm in size who underwent surgery following radiation therapy (179).

There have been many series published over the last several years reporting institutional experiences with chemoradiation followed by surgery (392–406). Comparison of these studies is difficult given their heterogeneity with respect to disease stage, chemotherapy regimen, external beam radiation dose, brachytherapy administration, and type of surgery. Nonetheless, the pelvic recurrence rate, DFS, and OS appear to be comparable to those of women receiving chemoradiation in several of these studies. Importantly, complications related to the genitourinary tract, gastrointestinal tract, and lymphatics may be increased especially in those women who underwent a radical rather than simple (extrafascial) hysterectomy (403,404). Recently, the results of the French GYNECO 02 randomized trial were published (407). Begun in 2003, this trial was closed prematurely due to poor accrual after only enrolling 61 of the anticipated 320 patients by 2006. Given the limited size, this study was underpowered. Nonetheless, women with Stage IB2–II disease with a clinical and radiographic complete response following chemoradiation were randomized to hysterectomy or no further treatment. Though this

study was underpowered given its limited size, there was no significant difference in the 3-year event-free or OS with a median follow-up of 3.8 years (407). Therefore, given these results and given that there appears to be a higher incidence of complications with surgery following chemoradiation, state of the art chemoradiation remains the standard of care in women with locally advanced cervical cancer (408).

Adjuvant Chemotherapy

The use of adjuvant chemotherapy for women with cervical cancer has been studied in both early-stage disease and locally advanced disease (409,410). In early-stage disease, adjuvant therapy with radiation, often in combination with chemotherapy, has been administered to women who are at intermediate or high risk for recurrence following surgery (409). In locally advanced disease with a 5-year OS of 66%, adjuvant chemotherapy after chemoradiation has been administered with the aim of decreasing distant metastases and increasing survival (410,193). Presently, the role of adjuvant chemotherapy in early stage and locally advanced cervical cancer is also being investigated in ongoing clinical trials.

In early-stage IA2, IB1, and IIA cervical cancer, a meta-analysis of 3 randomized controlled trials compared radiotherapy versus cisplatin-based chemoradiation after RH in women with at least 1 of the following risk factors for recurrence: (a) lymph node metastasis; (b) positive surgical margin; or (c) microscopic involvement of the parametrium; (d) deep stromal invasion (>10 mm); (e) LVSI; or (f) nonsquamous histology (411). Although these studies were small with limited follow-up, the results suggested a clinical benefit from the addition of chemotherapy to radiotherapy. Two of the trials in this meta-analysis compared chemoradiation versus radiotherapy alone in 325 women and found that adjuvant cisplatin-based chemotherapy significantly reduced the risk of death and disease progression. The trial by Peters et al. consisted of 268 of the 325 patients and has been considered the definitive trial for the use of cisplatin-based chemoradiation for patients with early-stage cervical cancer at high risk for recurrence (142).

There are currently 3 ongoing randomized trials further investigating the role of adjuvant chemotherapy in early-stage disease (412–414). In women with Stage I–IIA cervical cancer and intermediate risk of recurrence, a randomized controlled trial (Korean GOG 1008/GOG 0263, NCT 01101451) is comparing postoperative adjuvant chemoradiotherapy with radiation therapy alone after treatment with RH (412). In women with high risk of recurrence, the addition of adjuvant chemotherapy is now being explored in two randomized controlled trials. The first, NCT00980954 (Radiation Therapy Oncology Group/GOG 0724), is comparing adjuvant paclitaxel and carboplatin after chemoradiotherapy versus chemoradiation in women with Stage IA2, IB, or IIA disease (413). The second, NCT 00806117 (Sun Yat-sen University, China), is a 3-arm study comparing radiotherapy versus chemoradiation versus sequential therapy (paclitaxel and cisplatin, followed by radiation therapy, and then adjuvant paclitaxel and cisplatin) in women with Stage IB–IIA disease. Results of these prospective trials will help determine the benefit of adjuvant therapy following RH for women with early-stage disease at risk for recurrence (414).

Adjuvant chemotherapy has also been used following concurrent chemoradiation in locally advanced cervical cancer, although supporting data have been limited (142,193,415). Within the meta-analysis that reviewed 18 trials comparing chemoradiotherapy to radiotherapy alone for primary treatment of locally advanced carcinoma of the cervix, 2 trials examined the addition of chemotherapy following chemoradiotherapy and found a greater survival advantage in this group (142,193,415). Recently, Dueñas-González et al. completed a Phase III trial in women with Stage IIB–IVA carcinoma of the cervix comparing

the standard concurrent chemoradiation with cisplatin versus chemoradiotherapy with cisplatin and gemcitabine followed by adjuvant cisplatin and gemcitabine (416). Patients in both groups received brachytherapy following chemoradiotherapy. Survival outcomes were improved in the adjuvant chemotherapy group and the increased toxicity was clinically manageable.

There are currently 2 ongoing trials further investigating the role of adjuvant chemotherapy in locally advanced cervical cancer. An international collaborative Phase III randomized trial (The Outback Trial, ANZGOG 0902, NCT 01414608) is examining the role of adjuvant carboplatin and paclitaxel chemotherapy following chemoradiotherapy (417). In this multicenter study, patients are stratified by stage (IB/IIA vs. IIB vs. IIIB/IVA), pelvic or common iliac nodal involvement, requirement for extended-field radiotherapy, age, and hospital/site. Patients with paraaortic lymph nodes above the common iliac nodes are excluded. However, a Phase I trial (GOG 9926, NCT 01295502) establishing the maximum tolerated dose and dose-limiting toxicities of adjuvant carboplatin (AUC 4 vs. 5) and paclitaxel chemotherapy following concurrent cisplatin-based chemoradiotherapy, includes women with Stage IB–IVA cervical cancer with positive paraaortic lymph nodes (418).

In summary, adjuvant chemotherapy has a role both in early-stage disease and locally advanced disease. Current clinical trials of adjuvant chemoradiation following radical surgery in early-stage disease and of adjuvant chemotherapy following chemoradiation in locally advanced disease will define its role in cervical cancer.

TREATMENT OF RECURRENT CARCINOMA OF THE CERVIX

General Considerations

The main cause of death among women with cervical cancer is uncontrolled disease in the pelvis. However, a subset of patients with recurrent disease confined to the pelvis following definitive therapy, whether that therapy is surgery or RT, are potentially curable. Treatment selection and the likelihood of success are functions of the primary therapy, extent of disease at presentation, site of recurrence, local extent of the recurrence, disease-free interval, performance status, and comorbidities.

When curative intent salvage treatment is contemplated, the local recurrence should be biopsy proven, and the patient should be evaluated for regional and distant metastasis by physical examination and imaging. A clinical diagnosis of pelvic sidewall involvement can almost always be made in the presence of a triad of sciatic pain, leg edema, and hydronephrosis. PET scanning may be the most accurate test in terms of assessing metastasis prior to embarking on local salvage therapy.

Generally, patients with pelvic or regional recurrences after definitive surgery alone are managed with RT or chemoradiation. Salvage options for patients with central recurrence after definitive or adjuvant RT are limited to radical, usually exenterative, surgery, and in selected patients, re-irradiation using interstitial radiation implants or highly conformal EBRT or IMRT. Chemotherapy-responsive patients can obtain meaningful palliation in many cases.

Salvage Treatment After Definitive Radiation Therapy: Interstitial Re-irradiation

Recurrent cervical carcinoma following definitive RT within previously irradiated areas presents a difficult management problem.

FIGURE 21.23. **A and B:** Anterior-posterior and lateral views of a permanent interstitial implant done with Cs^{131} for a patient with locally recurrent cervical cancer several years after previous RT.

Although salvage surgery, usually exenterative, can be offered to patients with limited, centrally recurrent lesions if age and general condition permit, radical surgery following RT is accompanied by operative mortality in some, severe morbidity in many, and substantial loss of structure and function in all. Therefore, the applicability of salvage surgery is limited by physician and patient acceptance, as well as by clinical parameters. Even among patients meeting rigorous preoperative criteria, salvage surgery will be aborted in about one-fourth of patients.

Previously irradiated tissues do not have the same tolerance as unirradiated tissues. Therefore, severe late effects have been observed in the re-irradiation setting, particularly in older series that predominantly used external beam techniques in poorly selected patients. More recently, evidence has been presented to suggest that re-irradiation can be curative in a significant percentage of patients with small-volume central recurrences, particularly when there has been a long disease-free interval since the earlier diagnosis and treatment.

Randall et al., in a series of 13 patients, observed a 69% complete response rate and a 46% NED (no evidence of disease) rate with a minimum 2-year follow-up, and median follow-up of 59 months (419). Interstitial re-irradiation (IRI) doses of 30 to 55 Gy were employed, with low-dose-rate permanent and temporary implants. Patients with squamous histology did significantly better than patients with adenocarcinoma histology. Other predictors for improved outcomes included smaller tumor volumes, higher implant doses, and vaginal wall/suburethra versus vaginal cuff location. Late morbidity was limited to one recto-vaginal fistula in a patient who also had recurrent tumor.

Brabham and Cardenes reported the Indiana University experience of 19 patients who underwent interstitial re-irradiation with gold-198 as salvage treatment for recurrent gynecologic cancers after previous RT. With a median follow-up of nearly 2 years, the complete response rate was 95% and the local control was 63%. Over half the patients were alive with NED at the time of the analysis. Only one self-limited toxicity was observed. The control rate did not seem to be affected by histology or tumor volume (420).

Although gold-198 has excellent properties as a permanent interstitial isotope for re-irradiation, its major drawback is its high energy, resulting in some radiation exposure for staff. An alternative permanent seed isotope, Cesium-131, has recently been introduced. This isotope has a short half-life (9.69 days) and low mean

energy (30 keV). It has been shown that similar dose distributions are achievable with both isotopes, although Cs^{131} results in significantly enhanced radiation safety (421) (Fig. 21.23).

Jhingran has described the use of external beam IMRT in the re-irradiation setting (291). In particular, IMRT can treat pelvic recurrences that cannot be treated with brachytherapy, because of size, location, or other factors.

Compared to exenterative surgery, re-irradiation is better tolerated acutely, has little operative mortality, and often preserves structure and function of pelvic organs. When contemplating re-irradiation, it is important to analyze the techniques used in the initial treatment (beam energy, volume, doses delivered with external or intracavitary irradiation). The period of time between the 2 treatments must be taken into consideration.

Re-irradiation, in particular IRI, is under-utilized in the management of locally recurrent cervical cancer. As chemotherapy does not have curative potential and many patients will not be candidates for exenterative surgery or will refuse such surgery, re-irradiation, in many cases, will be the only feasible curative intent therapy. Patient selection and careful brachytherapy technique are crucial to successful re-irradiation.

Recurrence in the Paraortic Chain

Although unusual, recurrences limited to the PANL region are reported following primary surgery or RT. Grigsby et al. reported a 100% salvage rate in patients with isolated paraortic recurrences if the recurrences were asymptomatic and discovered by imaging follow-up, and received full-dose (>45 Gy) salvage RT combined with chemotherapy (422). This observation was confirmed by the experience reported by Kim et al. (423). These investigators treated 12 patients with isolated paraortic failures following RT with concurrent chemotherapy (mostly paclitaxel) and hyperfractionated RT. In patients who relapsed within 24 months of their initial treatment, the median survival following attempted salvage was 13 months. In contrast, patients having a disease-free interval greater than 24 months had a median survival of 45 months with this therapy. Niibe et al. conducted a multi-institutional retrospective analysis of 84 patients with isolated paraortic node recurrences treated with RT. The 3- and 5-year OS rates were 50% and 31%, respectively (424). A significant difference in 3-year OS was observed between symptom-positive and symptom-negative

patients, 28% versus 56%, respectively ($p = 0.018$). Three-year OS rates were 43% for patients treated with ≤ 50 Gy and 58% for those with ≥ 51 Gy ($p = 0.07$).

Salvage Treatment After Definitive Radiation Therapy: Radical Surgery

Pelvic Exenteration

Advances in perioperative and postoperative care and better techniques of pelvic, urinary, and GI reconstruction have led to much improved outcomes and enhanced quality of life compared to early experiences with pelvic exenteration (PE). Survival rates have increased from 20% to about 60% with an average of 40% to 50% 5-year survival in reported series of patients completing the procedure.

Despite these advances, PE is still a very morbid operation with acute and late complications reported as high as 50% to 60% and a mortality rate of 5% to 7%. The procedure is most commonly used in patients with recurrent central pelvic disease after treatment with pelvic RT. Historically, one-third of patients explored for PE will have the procedure abandoned. In some cases patients with stage IVA disease may be offered primary PE, although modern chemoradiotherapy is probably preferred.

In patients undergoing PE, Marnitz et al. noted the importance of margin status: 5-year survival was 55% with negative margins compared to 10% if margins were positive (425). Given this fact and the potential morbidity and mortality from the procedure, proper patient selection requires that all efforts be made to assure that there is no site of metastatic disease and the isolated central recurrence can be resected with negative margins. Additional negative prognostic factors include disease-free interval less than 1 year, size of recurrence greater than 3 cm, lymphatic spread, and parametrial and sidewall involvement. Patients with positive nodes have a survival rate of 20% or less. The presence of grossly positive lymph nodes during exploration is a poor indicator for survival and should be considered a contraindication to exenteration. The use of PET/CT technology may assist in detecting occult metastatic disease prior to consideration of TPE (286).

Berek et al. reported 75 patients older than 45 years who underwent PE at a single institution. The operative time averaged 7.76 hours, the mean estimated blood loss was 2.5 liters, and the median length of stay was 23 days. Morbidities included intestinal fistulae in 15%, urinary fistulae in 8%, early bowel obstruction in 11%, and late bowel obstruction in 22%. When a J-pouch was used for colonic re-anastomosis, there was no reported fistula. Survival for patients with cervical and vaginal cancers was 73% at 1 year, 57% at year 3, and 54% at 5 years (426).

A recently published large series with long follow-up found 1-, 2-, and 4-year survivals to be 64%, 44%, and 34%, respectively (427). As in most series, the 54 patients in this series included only those patients who actually had an exenteration, excluding those in whom it was attempted but not performed. A larger series of 106 patients was reported from Italy. With a median follow-up of less than 2 years, the OS for the cervical cancer subgroup was 52%. The overall morbidity rate was 66%, with nearly half of patients experiencing early and late complications. Among the complications, 70% were urinary tract and 25% were gastrointestinal, including bowel obstructions and fistulae (428). It appears that overweight and obese patients experience longer operative times and higher rates of wound separation than patients with normal weight, but the overall outcomes appear equivalent to normal-weight women (429).

Pelvic Reconstruction

In 1950, Bricker described a novel approach to diversion of urinary flow that involved isolating a segment of ileum, implanting

the ureters into this segment, and bringing an open end to the abdominal wall as a separate urostomy (430). This technique was a major advancement and significantly reduced complications compared to the wet colostomy (reimplantation of ureters in the colostomy that diverts the fecal stream). This form of urinary conduit is incontinent, where the urine drains continuously to an external reservoir. The other option is to create an internal reservoir using bowel wall with a continent mechanism that allows for self-catheterization, which negates the need for an ostomy bag and affords more control to a motivated patient. The most common complications of continent reservoirs are acute and chronic pyelonephritis, ureteral stricture, urinary leak, fistula, stone formation, and, rarely, renal failure.

The choice between continent and incontinent pouches depends most heavily on the surgeon's preference and the status of the distal ileum after RT. Penalver et al. reported complications in a series of patients undergoing construction of a Miami pouch. The early complication rate in 66 patients was 53% and included 10 ureteral stricture/obstructions, 4 anastomotic leaks, and 4 fistulae. An additional 5 had difficulty with catheterization, and 10 had pyelonephritis. Most complications were managed conservatively with antibiotics, percutaneous drainage, and nephrostomies. The operative mortality was 9%. The late complication rate was 37%. Out of 25 patients, 6 had strictures, 8 were incontinent, 7 had difficulty with catheterization, and 4 developed urinary stones. Again, most complications were managed conservatively (431). In a similar series from M. D. Anderson Cancer Center, 65% had postoperative complications related to the Miami pouch. Most complications were managed conservatively, and 90% retained normal continent conduit function (432).

Ungar and Palfalvi reported 29 patients who underwent orthotopic urinary reconstruction using ileocecal ascending colon reservoirs (the Budapest pouch). Although 77% of patients were able to void voluntarily without the need for self-catheterization, 23% to 47% had some incontinence (433). This is an attractive option as patients can potentially be free of any ostomies. However, only a select group of patients are candidates for these procedures.

The other component of pelvic reconstruction following PE is creation of a neovagina. Formation of a neovagina is an important component of reconstruction in several respects. For example, it fills the pelvis with well-perfused tissue and can significantly decrease the rate of pelvic infection and fistula formation. It also may restore some sense of normalcy in patients who are able to resume sexual activity after PE. Many options are available for construction of a neovagina. These include the following flaps: gracilis myocutaneous, anterolateral thigh fasciocutaneous, bulbocavernosus myocutaneous, transverse rectus abdominis musculoperitoneal (TRAMP) or myocutaneous (TRAM), vertical rectus abdominis musculocutaneous (VRAM), femoris myocutaneous, tensor fasciae latae myocutaneous, inferior gluteal, and omental J-flap. Portions of sigmoid colon have also been used. Myocutaneous flaps are favored due to better blood supply, ease of procedure, and functionality.

McCraw et al. first described the use of gracilis muscle for vaginal reconstruction (434). Ratliff et al. evaluated sexual adjustment in these patients and found that 52.5% never resumed sexual activity even though 70% were thought to have adequate and functional neovagina length on examination. Self-consciousness about urostomy and colostomy was the most common reason cited for avoiding sexual activity (435). Soper et al. reported on a "short gracilis" flap based on the terminal branches of the obturator artery and found no difference between the traditional and "short gracilis" flaps (436).

O'Connell et al. reported a 100% success rate with no fistula formation, bowel obstruction, or pelvic infection using VRAM flaps. Almost 50% of women reported sexual activity after VRAM (437). Soper et al. reported that 62% of women reported sexual activity within 12 months after VRAM or TRAM flap

reconstruction, concluding that both techniques give similar results and complication rates (438). Previous ligation of the inferior epigastric artery is an absolute contraindication of use of rectus flaps.

Sood et al. reported a modification to the VRAM using a smaller flap size anteriorly with a full-thickness skin graft placed posteriorly. One of 18 patients had a partial flap loss that resolved with conservative management, and 8 of 18 remained sexually active (439). This technique allows for a smaller abdominal wall defect with minimal compromise of the neovagina. Soper et al. compared gracilis muscle versus rectus abdominis flaps for vaginal reconstruction. Flap-specific complications and flap loss were significantly greater in gracilis muscle flaps. The authors have adopted rectus abdominis flaps as their preferred choice for vaginal reconstruction (440).

Re-anastomosis following rectosigmoid resection depends on many factors and is an option in patients undergoing suprallevator PE. Factors associated with anastomotic integrity include the length of remaining rectum/anus (<4 cm having a higher incidence of leaks versus >7 cm), blood supply to the region, and tension on the anastomosis. The use of low rectal anastomosis is controversial. Mirhashemi et al. found a 35% versus 7.5% rate of fistula formation or anastomotic breakdown in patients with previous RT compared to those who were radiation naïve. Protective colostomy was not associated with an improved outcome (441). Husain et al. reported a 54% anastomotic leak after low rectal anastomosis (442). This may be decreased by using a J-pouch instead of an end-to-end re-anastomosis (426). However, some patients have difficulty emptying the pouch, particularly with shorter pouch lengths.

No method of pelvic reconstruction is clearly superior to others or appropriate in all cases. The surgeon has many choices and should individualize according to each patient.

Radical Hysterectomy

Patients with very small central recurrences (<2 cm) after RT may be candidates for a less radical approach than PE, specifically RH. Maneo et al. evaluated the role of RH in patients with persistent or recurrent disease in 34 patients. They reported grade 3 to 4 toxicities in 44%, including 5 who developed fistulae. The overall 5-year survival was 49%, and 59% recurred with an average time to recurrence of 37 months. Patients with smaller tumors and lack of involvement of parametrium or vagina had better outcomes (443). Coleman et al. studied 50 patients treated with RH for persistent or recurrent central disease after RT. All patients with positive nodes died within 13 months. Severe toxicities occurred in 42%, and 28% developed either a GI or GU fistula. An additional 22% had ureteral injuries with 20% having severe long-term bladder dysfunction. The 5- and 10-year survival rates were 72% and 60%, respectively. Tumor size less than 2 cm was associated with a significantly greater survival compared to larger tumors. Overall recurrence rate was 48% (444).

RH may be a reasonable option for selected patients with persistent or recurrent central disease less than 2 cm with no extension to the parametrium or vagina. However, significant morbidity rates are relatively high.

Salvage Treatment After Previous Surgery—Definitive RT or Chemoradiation

Patients with pelvic recurrences after surgery alone are potentially curable. In particular, when recurrences are small and limited to the vagina and paravaginal tissues, salvage rates can be quite favorable, approaching 70% (445,446).

Concurrent chemotherapy with RT has proven beneficial in locally advanced cervical cancer. Several studies also suggest

a possible benefit in patients with recurrent disease. Grigsby reported a prospective trial of 22 patients with pelvic recurrences of cervical cancer following hysterectomy who received concurrent RT with 5-FU and cisplatin chemotherapy (447). None had received prior RT. The 10- and 15-year OS rates were 35%. Acute toxicity was limited; however, late toxicity was significant in some survivors, leading the author to recommend consideration of other chemotherapy regimens or RT alone.

In RT-naïve patients, pelvic RT of 40 to 50 Gy to the primary tumor and regional lymphatics is indicated. Inguinofemoral lymph node regions should be included in patients with involvement of the distal third of the vagina. The entire vagina should be treated in most patients with vaginal recurrences following hysterectomy. A vaginal dose of 60 to 65 Gy from external RT, with or without brachytherapy, is desirable. The gross tumor volume should receive additional radiation; doses of 15 to 30 Gy are administered with single, double-plane, or volume implants, or with intensity-modulated external RT. High-dose-rate brachytherapy techniques are also possible with appropriate dose modifications. Kotsuma et al. reported with the use of image-guided HDR interstitial brachytherapy for postoperative recurrences of 15 uterine cancers (including 9 cervical cancers) (448). The 3-year local control and survival rates were 78% and 77%, respectively. Two of 7 patients treated with a combination of EBRT and brachytherapy developed late complications.

Salvage Treatment—Intraoperative Radiation Therapy

Patients with microscopically positive or close margins have a poor prognosis after salvage surgery. Intraoperative RT (IORT) has been used in this situation to potentially sterilize residual disease after tumor debulking. IORT allows direct visualization of the target volume, and displacement and/or shielding of the surrounding normal tissues. The IORT dose is generally limited because of prior RT, proximity of critical normal structures, and the single fraction nature of the treatment.

IORT has been used for treatment of locally advanced and recurrent carcinoma of the cervix. Most of this experience is based on the treatment of isolated central and nodal recurrences, generally amenable to surgical excision. Limitations in evaluating IORT include small patient numbers, short follow-up, and widely varying patient selection criteria. The available data seem to indicate that IORT, although feasible, does not dramatically improve prognosis and is associated with significant incidence of long-term complications. Patients with limited central recurrences who are candidates for pelvic exenteration but are found to have unfavorable prognostic factors for local recurrence, such as close positive margins, LVSI, or perineural invasion, may benefit from IORT (449) or intraoperative interstitial brachytherapy (450).

SALVAGE TREATMENT – ROLE OF CHEMOTHERAPY AND TARGETED AGENTS

At this time, the role of chemotherapy and targeted agents in metastatic cervical cancer is palliative. While it is known that salvage treatment may prolong PFS, there are no randomized trials that compare systemic therapy with best supportive care and demonstrate that systemic therapy improves OS. However, given that systemic treatment does prolong PFS and may improve quality of life, women with good performance status should be offered further treatment.

There are several chemotherapeutic agents that are active as single agents in metastatic cervical cancer (367,368,451,452,453).

Over the past 3 decades, cisplatin has been the mainstay for treatment of metastatic disease with response rates of 18% to 38% depending on the dose and schedule, and with time to progression and median survival of less than 3 and less than 7 months, respectively (reviewed in 451,453). However, the frequent use of cisplatin as concurrent treatment with radiation in patients with locally advanced disease or as adjuvant treatment following radiation or surgery in patients at high risk of recurrence has contributed to a lower response rate when used in the salvage setting and suggested the need for nonplatinum agents (454,455). Other chemotherapeutic agents including capecitabine, carboplatin, docetaxel, 5-fluorouracil, gemcitabine, ifosfamide, irinotecan, oxaliplatin, mitomycin C, paclitaxel, pegylated liposomal doxorubicin, pemetrexed, topotecan, and vinorelbine have shown activity as single agents without a significant increase in objective response rates, and may be used in this setting (367,368,451–453).

To further evaluate the role of chemotherapy in metastatic disease, combination chemotherapy regimens have been investigated to improve the response rate and OS. In 2007, Hirte et al. published a systematic review identifying 15 randomized controlled trials of chemotherapy for women with recurrent, metastatic, or persistent cervical cancer (456). The data were unable to be pooled for a meta-analysis because of the clinical heterogeneity between trials, especially regarding the use of cisplatin in the primary treatment regimen. Outcomes were reviewed from 7 trials comparing single-agent versus combination cisplatin-based chemotherapy, 2 trials comparing combination cisplatin-based chemotherapy with nonplatinum agents, 3 trials evaluating regimens of other platinum-containing agents, and 3 trials evaluating nonplatinum agents. Their review showed that overall combination cisplatin-based chemotherapy was more effective than single-agent cisplatin. In particular, a Phase II randomized study demonstrated a survival benefit of cisplatin and topotecan over single-agent cisplatin in a population in which 57% of patients had previously been treated with cisplatin-based chemoradiation (455). Although there was increased toxicity with this regimen, it was not associated with poorer quality of life. Other reviews confirmed this analysis demonstrating a response advantage or improvement in PFS with combination chemotherapy when compared to single-agent cisplatin chemotherapy (367,368,451–453). Interestingly, Moore pooled data from 3 Phase III studies comparing single-agent cisplatin to cisplatin in combination with ifosfamide (GOG 110), paclitaxel (GOG 169), or topotecan (GOG 179) and performed a multivariate analysis to identify factors predictive of response and survival (453). The following 5 factors were identified as independently predictive of poor response: African American race, performance status greater than 0, pelvic disease, prior treatment with radiosensitizer, recurrence ≤ 1 year. Risk groups were determined according to the number of risk factors present (0 to 1 factors for low risk, 2 to 3 factors for mid-risk, 4 to 5 factors for high risk). Patients in the high risk groups had a predicted treatment response of only 13% and median PFS and OS of 2.8 and 5.5 months, respectively. The model was externally validated using the database on GOG 149, a study comparing cisplatin and ifosfamide with or without bleomycin (457). Nonetheless, they recommend further validation and pointed to a current Phase III GOG study (GOG 0240 NCT 00803062) as a source for this validation (458).

In 2007, the GOG established cisplatin and paclitaxel as the reference combination chemotherapeutic regimen for their future trials in the treatment of women with Stage IVB, recurrent, or persistent cervical cancer when they closed their Phase III randomized study (GOG 204, NCT 00064077) comparing cisplatin combined with either paclitaxel, topotecan, vinorelbine or gemcitabine to patient entry (459). After enrollment of 513 patients, a planned interim analysis by the Data Monitoring Committee recommended early closure for futility. The response rates were 29.1%, 25.9%, 22.3%, and 23.4% for the cisplatin

combinations with paclitaxel, vinorelbine, gemcitabine, and topotecan, respectively. The 3 cisplatin combinations were not superior to the control arm of cisplatin and paclitaxel with respect to OS, and there was a positive trend favoring the cisplatin and paclitaxel arm not only for response rate but also for progression-free, and OS (459). There was no difference in quality-of-life (QoL) outcomes between the cisplatin and paclitaxel arm and the other 3 combinations during treatment (460). While several retrospective studies have shown activity of carboplatin and paclitaxel, the results of the Japan Clinical Oncology Group's prospective, randomized Phase III study of cisplatin and paclitaxel versus carboplatin and paclitaxel (JCOG0505, NCT 00295789) presented at the American Society of Clinical Oncology Annual Meeting in 2012 and verified the equivalence of these regimens (461–466).

In this trial, paclitaxel 135 mg per m² over 24 hours and cisplatin 50 mg per m² were administered intravenously on days 1 and 2, respectively, as given in GOG 204, and compared with paclitaxel 175 mg per m² over 3 hr and carboplatin AUC 5, both administered intravenously on day 1. With a median follow-up of 17.6 months, this trial confirmed the noninferiority of carboplatin and paclitaxel to cisplatin and paclitaxel with respect to median OS (17.5 vs. 18.3 months, HR 0.994, noninferiority one-sided $p = 0.032$) and confirmed its tolerability and feasibility in the outpatient setting. In a subset analysis, this trial demonstrated that the combination of carboplatin and paclitaxel was particularly preferable to the combination of cisplatin and paclitaxel in patients with prior platinum-free intervals of ≥ 6 months.

The need to increase the response rate and OS in metastatic cervical cancer, particularly in women previously treated with platinum-based chemoradiation in the locally advanced cancer setting, has led to the investigation of nonplatinum doublets (467–469). Several Phase II trials nonplatinum doublet trials including paclitaxel in combination with topotecan and docetaxel in combination with gemcitabine have shown the response rates of 54% (7/13) and 28% (5/18), respectively (467,469). The results of Germany's Arbeitsgemeinschaft Gynäkologische Onkologie study (AGO-Zervix-1, NCT 01405235) randomized Phase III study investigating paclitaxel and topotecan versus cisplatin and topotecan are pending (470).

Several classes of targeted agents are also being investigated in metastatic cervical cancer (367,368,471,472). Epidermal growth factor receptor (EGFR) inhibitors have been of significant interest, given the ubiquitous presence of EGFR and its association with a negative prognosis in this disease (reviewed in 367,473). The EGFR inhibitor, gefitinib, was found to have minimal activity with only stable disease in 20% (6/28) of patients (474). Furthermore, the results of Phase II trials with other EGFR inhibitors, cetuximab and erlotinib, administered as single agents, revealed a PFS of 6 months or greater in 14.2% (5/35) and 3.6% (1/28) of patients, respectively, and again there were no responses (475,476). Even more disappointing was the response rate of 11.6% (8/69) with the combination of cetuximab with cisplatin (477). Though the response rate of cetuximab, topotecan, and cisplatin was 32% (6/19), the study was stopped prematurely due to excessive toxicity, including 3 treatment-related deaths (478). The results of the randomized Phase II study, Mito Cervix-2 (NCT 00997009), assessing the role of cetuximab with paclitaxel and carboplatin, are pending (479).

Anti-angiogenesis agents have also been investigated as targeted agents and have shown more promise than the EGFR inhibitors in metastatic or persistent cervical cancer. Single-agent bevacizumab demonstrated activity in this setting with a response rate of 10.9% (5/46) and a PFS of 6 months or greater in 23.9% of patients (480). Consistent with the activity of bevacizumab, the National Institute of Canada's Clinical Trials Group study with sunitinib (NCT 00389974), the multitargeted receptor tyrosine kinase inhibitor (TKI) of VEGF, platelet-derived growth factor receptor (PDGFR), c-kit, and FLT3, had a PFS of 6 months

or greater in 31.6% (6/19) of patients but had no objective responses. However, 5 patients (4 on-study and 1 3.5 months following discontinuation of study) developed a fistula (481). All 5 patients had received previous chemoradiation and the fistula occurred in the previously radiated field. A randomized Phase II study of lapatinib, the dual TKI of EGFR and HER2, versus pazopanib, the multitargeted receptor TKI of VEGF, PDGFR, and the c-kit, noted a response rate of 5.1% (4/78) with lapatinib and 9.5% (7/74) with pazopanib (482,483). Treatment with lapatinib in combination with pazopanib was the third treatment arm in this randomized study, but was discontinued due to an interim analysis which demonstrated increased toxicity and similar efficacy to lapatinib. Presently, a Phase II trial with brivanib, a potent dual inhibitor of VEGF and fibroblast growth factor receptor, is actively recruiting patients (484). In addition, a randomized Phase II study with cediranib, a VEGF inhibitor, in combination with carboplatin and paclitaxel is also actively recruiting patients (485).

The PARP inhibitors are another class of targeted agents actively being investigated in this disease. There are no single agent studies reported. Combination therapy trials with the PARP inhibitors, veliparib, and topotecan (NCT 01266447) or paclitaxel and carboplatin (NCT 01281852) and olaparib with carboplatin (NCT 01237067) are ongoing (486–488).

Utilizing platinum and nonplatinum doublets together with a targeted agent, the current Phase III randomized trial, GOG 240 (NCT 00803062) employed a 2×2 factorial design to investigate the doublets cisplatin and paclitaxel versus topotecan and paclitaxel, with or without bevacizumab. Interim analysis performed by the Data Safety Monitoring Board concluded that topotecan was not a superior substitute for cisplatin with paclitaxel chemotherapy by OS in this group. This study is closed to accrual at this time, and the final results concerning the tolerability and efficacy of these regimens are pending (458). Given the poor prognosis of patients with metastatic or recurrent cervical cancer and the limited efficacy with the presently available treatments, it is anticipated that randomized studies such as GOG 240 which include platinum and nonplatinum doublets with targeted agents will improve the response rate, PFS, and OS in women with this disease.

COMPLICATIONS AND SEQUELAE OF TREATMENT

Surgery Related

The most common complications with conization include infection, bleeding, damage to surrounding structures (bladder, rectum, vagina), and cervical incompetence with predisposition to preterm labor in future pregnancies. RH and lymphadenectomy may result in additional and somewhat unique complications. Urologic complications such as ureteral injuries and vesicovaginal or ureterovaginal fistulas are reported in 1% to 2% of cases, and this can be increased in patients requiring postoperative RT. Most vesicovaginal fistulas can be diagnosed with a voiding cystogram or clinically by infusion of a diluted methylene blue solution into the bladder and observation of leakage into the vaginal vault (commonly known as the “tampon test”). The majority will heal spontaneously with continuous bladder drainage for 6 to 8 weeks and treatment of any underlying infection. Ureterovaginal fistulas may be more difficult to diagnose. An IVP or CT scan may be indicated and demonstrate such a fistula in a patient with symptoms suggestive of a urinary fistula with a negative clinical exam or cystogram. Conservative management can include ureteral stenting and drainage of the urinary system via percutaneous nephrostomy, which may lead to healing of the fistula. Repeat imaging should be done prior to removal of

the stent to assure ureteral healing. Repair of a persistent vesicovaginal fistula can be attempted vaginally, depending on the site of injury. The fistulous tract is excised and repaired in multiple layers, followed by continuous bladder drainage and repeat cystogram to ensure surgical success. Ureteral fistulas that do not resolve with conservative management may require reimplantation of the ureter into the bladder (ureteroneocystostomy). Fistulas that occur following pelvic RT are less likely to heal with conservative management and may require earlier surgical treatment. As surgical repair after RT has a lower success rate, urinary diversion may be required as definitive treatment.

Averette et al. published their experience with RH in 978 patients over 25 years. The surgical mortality was 1.4%, and the urinary fistula rate was 1.4% (489). Artman et al. published their experience with RH in 275 patients over 21 years. The average blood loss was 1,800 cc. The urinary fistula rate was 2.6%, and the surgical mortality rate was 0.7% (490). Lee et al. reported a fistula rate of 2.4% and an operative mortality of 0.4% in a series of 954 patients. Lymphocyst formation is about 1.6% and the lymphedema rate is about 3.6% following PLD (491).

Located over the sacral promontory, the hypogastric plexus contains sympathetic fibers that fuse with parasympathetic fibers located in the parametrium and allows for bladder contraction and compliance. Surgical disruption of this plexus results in bladder atony and dysfunction in about 5% of patients, possibly requiring continuous or intermittent drainage for a few weeks (283).

Ralph et al. performed urologic evaluations in 40 patients at 2 weeks, 6 months, and 1 year after RH. At 2 weeks all had impaired bladder sensation and 68% had residual urine after voiding. At 1 year, 63% had impaired bladder sensation. Bladder capacity was lowest at 2 weeks (180 mL) and returned to baseline between 6 to 12 months. By 1 year, patients had residual urine after voiding. However, 62% had abnormal compliance and 85% used abdominal straining to void (492).

Rectal function can also be impacted by RH. Changes include altered relaxation of the internal sphincter, increased distention required to trigger relaxation, chronic straining, constipation, and decreased rectal sensation. Rectal dysfunction is frequently reported.

Levrant et al. evaluated the effects of obesity and age on RH outcomes. They reported no difference in survival or complications in obese versus nonobese patients. Similarly, age did not affect long-term complications and survival. However, patients older than 65 did have a higher incidence of postoperative ileus (493). Cohn et al. reported on 48 obese women (median body mass index [BMI] of 36 kg/m²) who underwent RH. Median blood loss was 800 cc, and the median number of lymph nodes obtained was 26. Margins were uninvolved in 98%. This study also confirmed the safety and efficacy of RH in selected obese patients (494).

Methods to decrease postoperative complications following RH have been suggested. Franchi et al. evaluated the role of pelvic drains following RH with LND in a randomized trial of pelvic drainage versus none. No difference was noted in lymphocyst formation or postoperative complications, suggesting that drains can be safely omitted following RH (495). The omental J-flap has been used in gynecologic oncology for pelvic reconstruction. Patsner and Hackett evaluated 140 patients who had an omental J-flap placed following RH. No urinary complications or infections were noted, even in patients who received postoperative RT (496). These data suggest that an omental J-flap may decrease postoperative complication rate, although there was no control arm for comparison.

Radiation Therapy-Related

Acute effects during external pelvic RT most typically include diarrhea and bladder irritation. These are usually self-limited

and can be managed effectively with conservative measures. Toita et al. reported the incidence of acute toxicity for patients entered in the prospective multi-institutional study (295). The only severe toxicities observed were 3 patients who experienced grade 3 leukopenia and 1 with grade 3 diarrhea. Physicians should keep in mind the risk of reduced locoregional control in patients who experience treatment delay caused by acute toxicity. Low-dose-rate (and pulsed LDR) implants require hospitalization and bed rest. At typical dose rates of 50 to 60 cGy per hour, implants typically last 2 to 3 days. During this time, there is the potential for acute problems related to or during the hospital stay. Jhingran and Eifel reviewed 7,662 implants in 4,043 patients, finding fatal or life-threatening complications to be exceptionally rare (497).

Commonly reported late sequelae of pelvic RT involve the rectosigmoid, small intestine, genitourinary tract, and vagina. Rarer sequelae include lymphedema, lumbosacral plexopathy, and pelvic insufficiency fractures. In contrast to acute effects, late sequelae are often permanent or require some intervention to improve. These complications usually occur within the first 3 years after RT. There is approximately a 5% rate of major late sequelae in patients with stage I cervical carcinoma treated with RT, and approximately 10% in patients with stages II–IVA disease. Grade 2 complications are seen in 10% to 15% of patients with all stages treated with RT alone (498,499). The risk is related to a number of factors, mainly dose and volume treated.

Perez et al. reported a less than 2% risk of severe small bowel toxicity when the pelvic sidewall dose was less than 50 Gy, and a 5% incidence with doses >greater than 60 Gy (164). In a multivariate analysis, Perez et al. found total doses to rectal and bladder points to significantly impact morbidity (499). Many investigators have found a significant relationship between radiation dose and complications. A greater incidence of pelvic complications has been consistently observed in patients treated with higher doses to the whole pelvis (above 40 to 50 Gy). Intracavitary dose does not correlate closely with severe complications.

Injury to the gastrointestinal tract is the most frequent late complication of RT for cervical cancer. A report by Eifel et al. (500) on 1,784 patients with stage IB carcinoma of the cervix indicates that the greatest risk is in the first 3 years after therapy. The risk of rectal complications declined after the first 2 years of follow-up to 0.06% per year. Nakano et al. reported long-term follow-up results for patients treated with definitive radiotherapy using HDR-ICBT (187). The median follow-up for surviving patients was 22 years. They demonstrated that the 10-year actuarial rates of major (grade 3–5) complications were 4.4% in the rectosigmoid colon, 0.9% in the bladder, and 3.3% in the small intestines. They showed that the incidence of major rectosigmoid complications moderately increased with follow-up beyond 5 years. The 5-year, 10-year, and 20-year actuarial rates of major rectosigmoid complications were 3.8%, 4.4%, and 5.3%, respectively. The rate of small intestinal complications also continually increased with longer follow-ups. The 5-year, 10-year, and 20-year actuarial rates of major complications involving the small intestine were 2.6%, 3.3%, and 8.3%, respectively (187).

Rectosigmoid complications include chronic proctosigmoiditis, rectal stricture, rectal bleeding, and rectal ulcer. Complications involving the small intestine include partial or complete obstruction, food intolerances, and malabsorption syndrome. Predisposing factors for injury, particularly to small bowel, include a history of abdominopelvic surgery and pelvic inflammatory disease. Accurate diagnosis is essential to proper management. It does not appear that specific symptoms have a reliable relationship to the underlying process (501). Major complications include intestinal obstruction, fistula formation, severe bleeding, and intractable diarrhea. Fortunately, these sequelae are relatively infrequent. These injuries generally result from fibrosis and ischemia secondary to the effect of RT on the small blood vessels and connective tissue. Conservative management might include a low residue diet,

antidiarrheal medications, and steroid or sucralfate enemas. Some cases of partial small bowel obstruction can be managed by bowel rest, decompression, and diet modification. Obstruction refractory to conservative management may require surgery involving intestinal resection or anastomoses.

Chronic urinary symptoms (urgency, incontinence, and frequency) are occasionally seen following RT. Genitourinary toxicity includes chronic cystitis, bladder contracture, and urethral stricture. Parkin et al. (502) reported a 26% incidence of these symptoms in patients treated with RT alone for cervical carcinoma. The authors found that the mean volume of full bladder sensation was significantly lower in the post-RT group than in the pretreatment group, as was the mean maximum cystometric capacity. Severe genitourinary toxicities secondary to RT include hemorrhagic cystitis and fistula, but these are rare. The latency period between RT and symptom onset is considerably longer for genitourinary than for gastrointestinal sequelae. In the longitudinal study by Eifel et al. (500), the risk of major urinary tract complications for survivors continued at 0.3% per year beyond 20 years. At 20 years, the actuarial risk of major complications was 14.4%. Nakano et al. also reported a similar time course (187). Lajer et al. prospectively gathered data regarding urologic morbidity in 177 consecutive patients treated curatively with RT (503). The 5-year actuarial incidences of grades 1 + 2 + 3, 2 + 3, and 3 were 62%, 32%, and 5%, respectively. In the long-term recurrence-free survivors, there was evidence of some reversibility of grade 1 and 2 morbidities.

Late sequelae involving the vagina include vaginal stenosis/fibrosis, dyspareunia, vault necrosis, and rectovaginal or vesicovaginal fistulae. Vaginal function can be affected by both radical surgery and RT. Surgery will shorten the functional length of the vagina, but pliability and transudative lubrication are often preserved. Radiation therapy can reduce length, caliber, and lubrication of the vagina; however, these symptoms can be alleviated in some patients with hormonal replacement and vaginal dilatation. Although some gynecologists feel that radical pelvic surgery may affect vaginal function to a lesser degree than RT, a large Swedish study found that the type of treatment had virtually no effect on the prevalence of vaginal changes and sexual distress (504). Huh et al. also demonstrated that there was no difference in sexual dysfunction between surgery and radiotherapy (505).

Postradiation fistula rate is about 2%. Fistulae can be difficult to manage, as most will not heal spontaneously, and local corrective procedures may prove unsuccessful (506). Patients with large fistulae may require diversion. Factors that may increase the rate of fistula are combined treatment (surgery and RT), advanced stage of disease, high rectal dose, smoking, thin habitus, inflammatory bowel diseases, diabetes, and other vasculopathies. Feddock et al. reviewed 24 patients with fistulae in the setting of cervical cancer, out of a 495 patient cohort. Six were present at diagnosis, 6 were in the setting of recurrent disease, and 12 developed following treatment. Among these 12 patients, 9 (75%) developed the fistula following a biopsy that was negative for tumor, with a median time to fistulization of 4.5 months (507). Postradiation biopsies should be taken only in the setting of a high index of suspicion, when the results will affect management, and with appropriate caution.

Although extremely rare, lumbosacral plexopathy has been occasionally reported in patients treated for pelvic tumors with doses of 60 to 68 Gy. Characteristically, these patients have lower motor neuron weakness of the legs combined with loss of deep reflexes and muscular fasciculation. Separating lumbosacral plexopathy from recurrent tumor is sometimes difficult. Generally, weakness is more prominent in radiation-related plexopathy, and pain is more frequently seen in tumor-related cases. Muscular weakness, numbness, and paresthesias are common in both groups.

Insufficiency fracture occurs with normal stress in bone with diminished elastic flexibility, a condition that can exist in irradiated bones. The usual presenting symptom is moderate to severe pelvic pain. Differential diagnosis can include metastatic disease,

tumor recurrence, second malignancy, and benign causes. Because symptoms can resolve with conservative management, proper diagnosis is important. Ikushima et al. reviewed 158 patients with gynecologic malignancies who received whole-pelvis RT. Eighteen patients (11%) developed insufficiency fractures in the irradiated field (508). Oh et al. retrospectively evaluated the incidence, clinical characteristics, and risk factors of pelvic insufficiency fractures after whole-pelvis RT in 557 patients with cervical cancer (509). The 5-year cumulative incidence of fracture was 19.7%, most commonly involving the sacroiliac joint. Multivariate analysis demonstrated that age ≥ 55 years, body weight less than 55 kg, curative treatment, and dose ≥ 50.4 Gy were statistically associated with the development of insufficiency fractures.

High doses of RT cause obliterative endarteritis, reactive fibrosis, and decreased vascularity and oxygenation. As a result, soft-tissue injury can occur, and this can be particularly problematic in the treatment of cervical cancer extending to the distal vagina. Careful attention to radiation planning and dosimetry, careful blocking, and avoidance of unnecessary dose to the perineum during both external beam RT and brachytherapy will make these complications less common. Although these injuries can cause pain that can be difficult to distinguish clinically from recurrent disease, the possibility of radiation injury should be kept in mind, because it is advisable to try to avoid deep biopsies or other trauma to tissues in which perfusion is compromised (507). For refractory radiation-related ulceration and necrosis of the vagina, vulva, and soft tissues, hyperbaric oxygen therapy has been used with some success (510,511).

Combined Modality Related

Irradiation Followed by Surgery

In a GOG study reported by Keys et al., 256 patients with stage IB carcinomas of the cervix ≥ 4 cm confined to the cervix were treated with either external RT and intracavitary

irradiation, or with external RT and a lower dose of intracavitary irradiation followed by an extrafascial hysterectomy. The toxicities were similar in both groups, with grade 3 and 4 toxicities of about 10% in each arm (179). Meticulous, sharp dissection is recommended in the performance of extrafascial hysterectomy following preoperative RT.

Coleman et al. studied 50 patients managed with RH for persistent or recurrent disease limited to the cervix after pelvic RT. Severe toxicities occurred in 42%, and 28% developed GI or GU fistulae (444).

Surgery Followed by Irradiation

Radical pelvic operations commonly result in intestinal adhesions to denuded surfaces in the pelvis. When postoperative RT is given, complications are more likely. A significant increase in grade 2 to 4 late complications following RT is seen among patients undergoing pre-RT surgical staging, particularly with a transperitoneal approach compared with a retroperitoneal approach. Pretreatment laparotomy increased the rate of fistula formation (5.2% vs. 2.9%) as well as small bowel obstruction (14.5% vs. 3.7%) (500). An extraperitoneal approach to lymph node staging purposes lessens these complications.

In a randomized study of postoperative RT versus no further treatment (NFT) after RH, Sedlis et al. found that grade 3 to 4 GU toxicities occurred in 3.1% in the RT versus 1.4% in the NFT arm. Grade 3 to 4 GI toxicities were 3.1% versus 0.8%, respectively. The overall grade 3 to 4 toxicity was 6% in the RT group versus 2.1% in the NFT arm (369). Kim et al. presented an analysis of 800 patients with stages IB-IIIB cervical cancer who received postoperative RT following RH and bilateral salpingo-oophorectomy (BSO). With a median follow-up of 100 months, the incidence of late injuries (grade 3 to 4) were 1.6%, 1.4%, and 1.0% for rectum, bladder, and small bowel, respectively (372).

Methods to decrease the volume of small bowel irradiated will further lessen enteric morbidity. Figures 21.24 and 21.25

FIGURE 21.24. Lateral radiographs with and without bladder distention in a patient with contrast in small intestine.

FIGURE 21.25. A and B: Anterior–posterior radiographs with and without bladder distention in a patient with contrast in small intestine.

show the effect of treating patients in the prone position with a full bladder as a means of limiting the volume of small bowel irradiated. Similarly, IMRT techniques can also be used to limit doses to normal tissues (Figs. 21.14 and 21.16) (291).

Concurrent Chemoradiation

The concurrent administration of chemotherapy and radiotherapy for women with locally advanced cervical cancer results in both acute and late complications. In 2005, a meta-analysis compared the effectiveness of concurrent chemoradiation to radiotherapy in 24 randomized trials involving 4,921 women treated in the 1980s and 1990s (512). Acute toxicities were analyzed on data from 17 trials, of which 15 were published and 2 unpublished. In all trials, the reported number of deaths from acute toxicities was 7. Six of these occurred in the women treated with chemoradiation (1 neutropenic sepsis and 5 unspecified treatment-related deaths). Four deaths occurred on 1 unpublished trial and were felt to be related to the chemotherapy dose which was modified. In review of both the hematologic and nonhematologic toxicities, there were statistically significant increases in all grades of toxicities in the chemoradiation arm compared to the radiation arm. The nonhematologic toxicities included gastrointestinal (nausea, vomiting, and diarrhea), skin, and neurologic toxicities. Most commonly, these toxicities were self-limiting or amenable to medical treatment. Late toxicities, defined as toxicity that occurred or persisted 3 months (90 days) after the start of radiation therapy, were reported in 12 of the 24 trials. There were eight deaths due to late toxicities. Four deaths in the chemoradiation arm were due to 1 patient each with small bowel obstruction and perforation, bilateral ureteral obstruction and fibrosis and 1 renal failure, late gastrointestinal event, and unspecified toxicity. Four deaths in the radiation arm were due to 3 patients with bowel late events and 1 with radiotherapy-related fistula. The most commonly reported late toxicities involved the gastrointestinal or genitourinary tract (512).

In 2010, the meta-analysis reported in 2005 was superseded by an updated meta-analysis of these data by the Chemotherapy for Cervical Cancer Meta-analysis Collaboration (387). While 18 trials were used in this meta-analysis for various outcomes, only data from 16 and 7 trials were used for the acute and chronic toxicity analyses, respectively. For patients receiving chemoradiation therapy, there was a significant increase in white blood cell and gastrointestinal toxicities. Few serious

events were recorded for acute toxicity in hemoglobin or platelet values and genitourinary or skin toxicities. As a result, no formal analyses were performed. While data on late toxicities were available, insufficient data were available to assess whether serious late toxicity was affected by the type of treatment (387).

An audit by the Royal College of Radiologists in the United Kingdom was performed to compare the survival and late complications among women treated with chemoradiotherapy and radiotherapy (513,514). During 2001–2002, 1,243 patients from 42 centers were treated with radical chemoradiation (472), radical radiation alone (355), surgery with postoperative radiotherapy (249), or nonradical treatment (168) for locally advanced cervical cancer. Death due to complications from treatment was noted in 6 women treated with chemoradiotherapy and no women in the radiotherapy group. There was no difference in the grade 3 and 4 gastrointestinal and genitourinary late complications in women receiving chemoradiotherapy (10%) versus women receiving radiotherapy alone (8%). Of interest was the timing in both groups for development of these serious late complications. Within the first 3 years after treatment, approximately 50% of the bowel toxicity and 60% of the bladder toxicity had occurred in patients receiving chemoradiotherapy, whereas nearly all the bowel and bladder toxicity had occurred in the radiotherapy alone group. Furthermore, serious complications developed up to 7 years after treatment in the chemoradiation group. Despite this, these authors reported that there was no apparent increase in overall late complications in women receiving chemoradiotherapy compared with radiotherapy alone (513).

Several case reports of unusual late complications including subacute neurologic toxicity, uterine necrosis, and multiple bowel stenoses with perforation have been reported in women following chemoradiation (515–518). In addition, a case report of acute myelogenous leukemia occurring 5 years after treatment with cisplatin-based chemoradiation has been reported (519).

Thromboembolic Complications

The incidence of venous thromboembolic complications in women with cervical cancer varies from 0% to 34% (520–522). Risk factors for venous thromboembolism are attributed to the classic Virchow triad of hypercoagulability, venous stasis, and endothelial injury. Barbera and Thomas have written a comprehensive review on venous thromboembolism in cervical cancer

and divided the risk factors further into patient, tumor, and treatment-related factors (520). They reported that many of these factors related to Virchow's triad.

There are no published reports of patient-related risk factors in cervix cancer (520). However, in other cancers, these risk factors may include age, body mass index, immobilization, previous venous thromboembolism, and Factor V Leiden deficiency or prothrombin 2010A gene mutation (520,522). Tumor-related risk factors include histologic cell type, tumor production of prothrombotic substances, and cancer stage (520). Stage has been associated with venous thrombosis because stage in cervical cancer is defined by extent of tumor spread to the pelvic sidewall or parametrium, and this extension may cause compression of the pelvic veins and venous stasis. However, the most common risk factors for venous thromboembolism are treatment-related risk factors associated with surgery, radiotherapy, chemotherapy, and biologic therapy (520–522).

In reviewing treatment-related risk factors for venous thromboembolism, surgery has accounted for up to 17% incidence (520,522). EBRT is also felt to be a risk factor for venous thromboembolism, though it has not been as well studied as the incidence with brachytherapy, which ranges from 0% to 17% (520).

In addition, women undergoing low-dose rate brachytherapy may also be at risk due to bed rest and immobilization required for this therapy. Chemotherapy alone or in combination with radiotherapy has been associated with venous thromboembolism (520–522). Erythropoietin-stimulating agents administered with radiotherapy or concurrent chemoradiation have been thought to increase the risk of venous thromboembolism and are not encouraged (121,122,523–526). In a randomized trial of chemoradiation with or without erythropoietin-stimulating agent for patients with locally advanced cervical cancer and hemoglobin levels less than 14 g/dL, the trial was closed prematurely with less than 25% of the planned accrual due to concerns of a potential increased risk of VTE with the use of erythropoietin-stimulating agents (122). At the time of study closure, the incidence was 7.7% (n = 52) in the control group and 19.3% (n = 57) in the erythropoietin-treated group, with an overall incidence of 13.8%. There was no significant increase in the treated group. Finally, anti-angiogenesis agents are known to increase the incidence of venous thromboembolism in patients with cancer (472,527). Several of these agents are presently under investigation and are demonstrating promising activity in treatment of cervical cancer (472).

Corpus: Epithelial Tumors

D. SCOTT McMEekin ■ CATHERINE YASHAR
 ■ SUSANA CAMPOS ■ RICHARD J. ZAINO

Endometrial cancer (EC) accounts for nearly 50% of all new gynecologic cancers diagnosed in the United States. It is the fourth most common malignancy in women, and the eighth most common cause of cancer death. The American Cancer Society (ACS) estimated that there were 47,130 new cases of endometrial carcinoma and 8,010 deaths from advanced or recurrent disease in 2012 (1). The death rate per 100,000 women from all malignancies in the United States was 160.49, with uterine cancers contributing at a rate of 4.13 (1). Worldwide, EC is only second to cervical cancer in frequency. The ACS reported that the incidence of EC rose 13% from 1987 to 2012; however, the numbers of deaths rose ~250% in the same time period. Endometrial carcinoma occurs most often in the sixth and seventh decades of life, with an average age at onset of 60 years. It is estimated that 75% to 85% of the cases occur in patients 50 years old and older, and 95% occur in patients over 40 years of age (2, 3). The disease, although reported in patients as young as age 16 years, is rare in patients younger than 30 years of age.

EC is commonly confined to the uterus at diagnosis. Data from the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) program demonstrated that Stage I disease was found in 73% of patients, and 10% had Stage II disease (4). The 26th Annual Report of the International Federation of Gynecology and Obstetrics (FIGO) on 9,386 EC patients demonstrated that 83% of patients were Stage I or II (5). With the favorable disease distribution at presentation, it is not surprising that most patients have a favorable prognosis. Results from FIGO show that 85% to 91% of Stage I patients are alive at 5 years, and patients in the SEER database with localized disease have 96% 5-year survival (4, 5). As a result, EC has been considered a "good cancer"; that is, most patients present with early-stage, highly curable disease. Despite the favorable characteristics for most patients, those with high-risk factors, including increased age, higher tumor grade, aggressive histology, and advanced stage, face real challenges.

The management of EC has undergone continued evolution. In the past, most patients received some form of pre- or postoperative radiation in combination with a simple hysterectomy. With a better understanding of the relationship between uterine factor and risk of nodal disease and recurrence, selective use of surgical staging was integrated. This was followed by an era where, increasingly, surgical therapy expanded to include routine use of pelvic and paraaortic lymphadenectomy. Minimally invasive techniques were studied and have been routinely adopted into the management of women with EC. Today, greater emphasis is being placed on the selection of particular patients for whom lymphadenectomy may best offer better outcomes, and whose avoidance may result in less morbidity. Understanding tumor biology as it relates to predicting recurrence and survival, and how genetic changes can be exploited to direct postoperative therapies, represent our current challenge. Over 10 years ago,

the National Cancer Institute convened an expert panel to develop a national 5-year plan for research priorities in gynecologic cancers. The resulting report, Priorities of the Gynecologic Cancer Progress Review Group (PRG), specified that understanding tumor biology was the central key toward controlling gynecologic cancers. For EC, one of the top research priorities defined by the PRG was to identify prognostic and predictive markers for treatment efficacy and toxicity. In a 2006 State of the Science Meeting, in Manchester United Kingdom, a series of research questions on prevention, adjuvant treatment, and treatment of advanced or recurrent disease were proposed setting the stage for a clinical trials agenda over the next 5 years (6). In 2011, the Society of Gynecologic Oncologists conveyed a panel of experts that produced a report "Pathway to Progress in Women's Cancers". That report detailed areas of research, by disease site, on which the women's cancer community should focus for the next decade. For EC, the suggested road map for the future of women's cancer care research would include research related to obesity, predicting risk of metastatic disease, targeting therapy based on risk factors and molecular characteristics of disease, and cost-effective care to suggest prioritization of research strategies (7).

Current clinical controversies center on identifying which patient populations might benefit most from lymphadenectomy, developing alternatives to performing lymphadenectomy, and creating risk models to assist with selection of patients who may benefit most from adjuvant therapies. While we suspect that an increased use of surgical staging has translated to a better understanding of risk, data also suggest that despite negative nodes, uterine factors play a significant contribution to risk of recurrence. Current trends also suggest a less frequent use of pelvic radiation therapy or no use of any radiation (8). There have been important developments in chemotherapy in EC. Combination chemotherapy is increasingly used in the primary management of advanced and recurrent disease, and may hold promise in an adjuvant setting. How to best integrate radiation therapy and which specific techniques to consider are being studied in going clinical trials. Hormonal therapy remains an important option and our understanding of steroid receptors at a molecular level may help to determine which patients may benefit most (9). Enhanced understanding of biologically relevant targets has fostered the development of new classes of agents that attempt to exploit susceptible pathways in tumor cells, and targeted agents are being integrated into large clinical trials (10, 11).

ANATOMY

The uterus is a fibromuscular pelvic organ situated between the bladder and the rectum, and enveloped by peritoneal reflections.

It is divided into the fundus, isthmus, and cervix. The uterine wall is composed of the outer smooth muscle myometrium and inner cavity lined by glandular endometrial epithelium with supporting stroma (endometrium). Five paired ligaments cover or support the uterus: broad, round, utero-sacral, cardinal, and vesico uterine. The utero-sacral and cardinal ligaments provide the greatest support within the pelvis and, contrary to cervical cancer, are infrequently involved with tumor spread. Blood is supplied to the uterus by the uterine artery, a branch of the hypogastric artery, which enters the wall of the uterus at the isthmus after it crosses over the ureter. It anastomoses with the ovarian artery in the ovarian ligament.

Malignant transformation of the endometrium is manifest in many fashions based on the anatomical relationships. Tumor growth may be confined to the endometrium, invade the underlying myometrium, penetrate to the uterine serosal surface or adjacent bladder or rectum, or extend into the cervical canal and invade cervical glands or stroma. Peritoneal disease spread may occur via transmigration from the fallopian tubes or through serosal penetration. Hematogenous spread is not uncommon in EC.

The lymphatics of the myometrium drain into the subserosal network of lymphatics, which coalesce into larger channels before leaving the uterus. Lymph flows from the fundus toward the adnexa and infundibulopelvic ligaments. The lymph flow from the lower and middle thirds of the uterus tends to spread in the base of the broad ligaments toward the lateral pelvic sidewall. There are four drainage channels from the uterus: from the fundus; in the folds of the broad ligament, along the mesosalpinx and fallopian tubes; and along the round ligaments. The drainage sites are principally reflected in metastatic potential to pelvic and paraaortic lymph nodes (LN), and occasionally involve inguinal nodes.

EPIDEMIOLOGY AND RISK FACTORS

The most important risk factor for the development of EC is age. EC is primarily a disease of postmenopausal woman, with median age at cancer diagnosis of 60 years (5). Approximately 85% of cases occur after the age of 50, the peak age-specific incidence is from 75 to 79 years (109 per 100,000), and only 5% of cases are from patients younger than 40 years of age (2, 3, 12). The ACS showed the probability of developing a uterine cancer to be one in 142 from age 40 to 59, one in 124 from age 60 to 69, and one in 78 from age 70 and older (1). Not unexpectedly, with an aging U.S. population, the total number of cases of EC has shown yearly increases, whereas the annual age-adjusted incidence rate peaked in the mid-1970s (33.8 per 100,000) and has remained stable at 23 to 25 cases per 100,000 women over the last 10 years (1).

Race also appears to play a role in the development of EC. The rates of EC are highest in North America and northern Europe, lower in eastern Europe and Latin America, and lowest in Asia and Africa (13). Factors accounting for these findings include differences in rates of obesity, use of hormone replacement therapy (HRT), and reproductive factors. In the United States, non-Hispanic White women have the highest age-adjusted incidence of EC at 25.4 (per 100,000 women), compared to women of African American (19.5), Asian (15.8), or Hispanic (17) heritage (14). African American women, however, have a much higher mortality rate (7.1 vs. 3.9 per 100,000) and lower 5-year survival (61% vs. 84%) compared to non-Hispanic White women. Relative survival in White women exceeds that for African Americans by at least 7% at every stage of diagnosis (1). In the 2012 ACS report, incidence rates of uterine cancers in White women were noted to have stabilized, but have increased by nearly 2% per year for African American women since 2004 (1).

Multiple explanations have been suggested to explain the differences in outcomes between racial groups, including differences in frequency of high-risk tumor types, differences in access to care (reduced use of surgery and radiation), and differences in medical comorbidities among races. Data from SEER demonstrated that African American women were more frequently diagnosed with higher stage, grade, and high-risk histologies than non-Hispanic White women, but there was no difference in the frequency of recommended therapy types between races (4). In two analyses of nearly 1,200 patients with advanced or recurrent EC participating in phase 3 chemotherapy trials conducted by the Gynecologic Oncology Group (GOG), African American race was independently associated with a lower likelihood of response to chemotherapy (relative odds of response 0.62) and decreased overall survival (OS) (hazard ratio [HR], 1.26) compared to White women (15, 16). These results suggest that racial disparity in outcomes exist even though patients were treated in similar fashion. Interestingly, one small study comparing microarray-based expression profiling between stage-, grade-, and histology-matched African American and Caucasian patients found no clear differences in global gene expression profiles, suggesting that environmental or social issues played a greater role in explaining disparity (17).

Most cases of endometrial carcinoma are thought to be sporadic; however, some cases clearly have a hereditary basis. The Lynch syndrome (hereditary nonpolyposis colorectal cancer [HNPCC]) is an autosomal-dominant cancer susceptibility syndrome associated with early-onset colon, rectal, ovary, small bowel, ureter/renal pelvis cancers, and EC. Lynch syndrome-related ECs account for 2% to 5% of all ECs, and occur in nearly 10% of women diagnosed with EC less than 50 years of age (18). The lifetime risk of EC in Lynch syndrome women is 40% to 60%, a risk similar to that of developing colon cancer. The risk of ovarian cancer is 10% to 12%. In about 50% of cases where patients have both colonic and gynecologic cancers (endometrial or ovarian), the gynecologic cancer precedes the diagnosis of colon cancer (19). The syndrome is most commonly due to germ-line mutations of one of the DNA mismatch repair genes *MSH2*, *MLH1*, or *MSH6*. In one study, 23% of EC patients diagnosed at less than 50 years of age with one relative having a Lynch type cancer had a mismatch repair gene mutation (20). Prophylactic hysterectomy and bilateral salpingo-oophorectomy has been shown to be an effective strategy for preventing ovarian and ECs in these high-risk patients (21).

Controversy exists regarding the relationship between *BRCA1* and *BRCA2* mutations and the risk of EC. Germ-line mutations of *BRCA1* and *BRCA2* account for a large proportion of hereditary breast and ovarian/primary peritoneal cancers. In 1999, Hornreich et al. presented a case report of sisters with the same *BRCA1* mutation who were diagnosed with serous carcinomas of the uterus and suggested a possible association (22). Several larger studies have attempted to address this hypothesis. In one study of 199 Ashkenazi Jewish patients with EC from a single institution, Levine et al. genotyped all patients for founder *BRCA1* and *BRCA2* mutations that existed in that patient population. The frequency of germ-line mutations (3 per 199, 1.5%) in EC patients was comparable to the baseline rate of 2% in the Ashkenazi population, suggesting no increased risk (23). In a large prospective study by Beiner et al., 857 known *BRCA1* and *BRCA2* carriers aged 45 to 70 were followed over time for the development of EC (24). With an average length of follow-up of 3.3 years, six women developed EC. Four of the six patients had used tamoxifen. Compared to the expected rate of EC in a general population, *BRCA* carriers who did not receive tamoxifen did not have a significant increase in risk of developing EC, whereas those patients who had received tamoxifen had a 11.6 incidence ratio ($p = 0.0004$). Barak evaluated 289 Jewish women with EC (80% type I, 20% type II tumors) for predominant mutations in Jewish populations (*BRCA1*, *BRCA2*, *MSH2*,

MSH6 selected mutations). Five women were found with *BRCA1/2* mutations, reflecting a rate similar to that seen in the general Ashkenazi Jewish population, and the authors indicated the data did not support screening in based on an EC diagnosis (25).

The clinical picture in endometrial carcinoma is as varied as are the associated risk factors for its development. One of the paradigms for bridging the gaps between epidemiologic, clinical-pathologic, and molecular factors seen in EC types is the relatively simple, yet attractive, classification system of ECs suggested by Bokhman in 1983 (26). ECs are thought to broadly arise from one of two different pathways: estrogen dependent or estrogen independent (Table 22.1). Based on the clinical and histologic features, ECs have been divided into type I and type II tumors. Type I tumors are more common (85%), tend to be found in younger women, and develop via a precursor lesion of atypical hyperplasia. These tumors are associated with a predisposing history of hyperestrogenism. They tend to be well differentiated and have minimal myometrial invasion, and as a result typically have a favorable outcome. Type II tumors account for a small percentage of endometrial carcinomas, occur in an older population, and frequently develop in the face of an atrophic endometrium. About half of all relapses occur in this group. Serous, clear-cell, and perhaps grade 3 tumors fit into the type II category. Despite the broad generalizations of the two categories, translational science data lend support for a separation into these groups at a molecular level. For example, mutations of *TP53* are common in uterine papillary serous carcinoma (UPSC), and rare in type I tumors (27). In type I tumors, *PTEN* mutations are common, but are rare with UPSC tumors. Global gene expression profiles have also been shown to be different between type I and II tumors (28).

Endogenous or exogenous exposure to estrogen is believed to be an important risk factor for the development of endometrial hyperplasia and type I cancers (29). Estrogens not opposed by progestins lead to increased mitotic activity of endometrial cells, resulting in more frequent errors in DNA replication and somatic mutations (30). These genetic changes are manifest clinically in endometrial hyperplasia and cancer. Estrogen excess as

an etiology for cancers is supported by epidemiologic features of the disease. Patients with chronic anovulation, nulliparity, early age of menarche, and late menopause have classically been identified with EC. Occasionally, endometrial hyperplasia or cancer develops in the setting of an estrogen-producing ovarian tumor (granulosa cell tumor) (31). The use of unopposed estrogens as part of hormone replacement strategies was first defined as an important risk factor in 1975 when the age-adjusted rate for EC peaked at nearly 33.8 per 100,000 (32, 33). A meta-analysis of 30 studies showed that the relative risk of ever users of estrogen therapy was 2.3 compared to nonusers, and it increased to 9.5 in users of 10 or more years (34).

Obesity is an increasingly common problem in the United States, and is estimated to account for 17% to 46% of EC incidence in postmenopausal women (35). Studies have shown that plasma concentrations of androstenedione and estrogens are correlated with body weight in postmenopausal women (36). Aromatization of androstenedione to estrone in adipose cells is believed to be the principal mechanism of excess estrogen production. While much of the data suggest that the relationship is strongest between estrogen exposure and type I cancers, Weiss et al. demonstrated in a case-control study that the risk of more aggressive tumors (higher grade or higher stage) was also seen with unopposed estrogen therapy, obesity, low parity, and history of diabetes. The authors suggested that the risk of EC was influenced by similar risk factors, regardless of tumor aggressiveness (37). Diabetes has also been associated classically with type I ECs (38, 39). Only non-insulin-dependent diabetes (type 2 diabetes mellitus [DM]), characterized by insulin resistance and elevated insulin levels, appears to be associated with EC (40). Hyperinsulinemia and higher levels of insulin-like growth factor 1 are thought to have neoplastic potential and, coupled with increased estrogen, are responsible for cancer development (41, 42).

Tamoxifen and Endometrial Cancer

Tamoxifen is a selective estrogen receptor modulator (SERM) with antiestrogenic properties in the breast, and estrogenic effects in tissues such as bone, the cardiovascular system, and the uterus. It has been used in prevention and treatment for all stages of breast cancer. An association with tamoxifen and EC was first reported by Killackey et al. in 1985 (43). The strongest data initially implicating tamoxifen use and the subsequent development of EC were published in 1989 by Fornander et al. (44). The investigators reviewed the frequency of new primary cancers as recorded in the Swedish Cancer Registry for a group of 1,846 postmenopausal women with early breast cancer who were included in a randomized trial of adjuvant tamoxifen. They noted a 6.4-fold increase in the relative risk of EC in 931 tamoxifen-treated patients compared to 915 patients in the control group. The dose of tamoxifen in this study was 40 mg/day, and the greatest cumulative risk of developing EC was after 5 years of tamoxifen use.

Fisher et al. published data regarding the association between tamoxifen use and the development of EC when they reported the findings of the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-14 trial (45). Data regarding the rates of endometrial and other cancers were analyzed on 2,843 patients with node-negative, estrogen receptor (ER)-positive, invasive breast cancer randomly assigned to placebo or tamoxifen (20 mg/day) and on 1,220 tamoxifen-treated patients registered in NSABP B-14 subsequent to randomization. The average annual hazard rate for EC in the placebo group was 0.2 out of 1,000 and 1.6 out of 1,000 for the randomized tamoxifen-treated group. The relative risk of an EC occurring in the randomized, tamoxifen-treated group was 7.5. Similar results were seen in the 1,220 registered patients who received tamoxifen. The mean duration of tamoxifen

Table 22.1 Comparison Between Type I and Type II Endometrial Cancers

	Type I	Type II
<i>Clinical Features</i>		
Risk factors	Unopposed estrogen	Age
Race	White > Black	White = Black
Differentiation	Well differentiated	Poorly differentiated
Histology	Endometrioid	Nonendometrioid
Stage	I/II	III/IV
Prognosis	Favorable	Not favorable
<i>Molecular Features</i>		
Ploidy	Diploid	Aneuploid
K-ras overexpression	Yes	Yes
HER2/neu overexpression	No	Yes
P53 overexpression	No	Yes
<i>PTEN</i> mutations	Yes	No
Microsatellite instability	Yes	No

therapy was 35 months, with 36% of the ECs developing within 2 years of therapy. Of the 23 cases of endometrial cancer developing while on tamoxifen, six cases occurred following less than 12 months of exposure, suggesting that some of the cancers may have been present prior to starting tamoxifen therapy.

Any conclusions drawn regarding the risks of tamoxifen treatment in inducing EC must weigh the benefits of tamoxifen in reducing breast cancer recurrence and new contralateral breast cancers. In the B-14 trial, the cumulative rate per 1,000 women with breast cancer relapse was reduced from 227.8 in the placebo group to 123.5 in the randomized tamoxifen-treated group. In addition, the cumulative rate of contralateral breast cancer was reduced from 40.5 to 23.5, respectively, in the two groups. Taking into account the increased cumulative rate of EC, there was a 38% reduction in the 5-year cumulative hazard rate in the tamoxifen-treated group. Thus, the benefit of tamoxifen therapy for breast cancer outweighs the potential increase in EC being reported.

The suspected mechanism for EC development following tamoxifen exposure is thought to be related to its estrogenic effects on the endometrium. As such, type I, low-grade/early-stage cancers would be expected. A report from the Yale Tumor Registry by Magriples et al. suggested that uterine cancers occurring in breast cancer patients on tamoxifen may behave more aggressively and carry a worse prognosis (46). Other studies, however, have not been able to confirm these findings (Table 22.2) (45, 47–49). It would appear from the available literature that there is no difference in the stage, grade, or prognosis of ECs associated with tamoxifen use.

More commonly, breast cancer patients are being managed with different strategies, which may reduce the impact of tamoxifen on EC risk. Next generation SERM agents, such as raloxifene, are effective in preventing breast cancer and reducing osteoporosis. In a large case-control study of women with (547 cases) and without (1,410 controls) EC, raloxifene users had a 50% reduction in risk of EC compared to nonusers, and tamoxifen users had three times the odds of developing EC compared to those who had used raloxifene (50). Compared to SERMs,

aromatase inhibitors prevent estrogen synthesis by inhibiting the conversion of androgens to estrogens. Third-generation aromatase inhibitors (anastrozole, letrozole, exemestane) are replacing tamoxifen for many breast cancer patients with ~50% of postmenopausal ER-positive patients receiving aromatase inhibitors (49). In clinical trials, compared to tamoxifen, aromatase inhibitors have lower incidences of vaginal bleeding or EC (50–53). In premenopausal patients, aromatase inhibitors have little activity, and tamoxifen will continue to have a role.

Protective Factors

Factors that reduce circulating estrogen levels (weight loss/exercise, cigarette smoking) appear to be protective against EC. Similarly, progestins antagonize the effects of estrogen on the endometrium and prevent the development of hyperplasia and cancer when added to estrogens (endogenous or exogenous). Combined estrogen–progestin HRT has been associated with reductions in the risk of EC in most, but not all, studies. Prior use of oral contraceptives also appears to be protective against the development of EC (54).

NATURAL HISTORY OF DISEASE

A better understanding of the natural history of EC has developed through evaluation of the patterns of spread. In a landmark study, the GOG performed a surgical pathologic study (GOG 33) in 621 patients with clinical Stage I–occult Stage II EC who underwent a standardized surgical procedure including exploration of the abdomen with biopsy of suspicious findings, collection of peritoneal fluid for cytologic evaluation, abdominal hysterectomy and bilateral salpingo-oophorectomy, and pelvic and paraaortic nodal dissection (55). The results of this study demonstrated important relationships regarding uterine tumor characteristics and spread of disease, and should be ingrained into the memory of those caring for patients with ECs.

Table 22.2 Clinicopathologic Data from Series Reporting on Tamoxifen-Associated Uterine Cancer

^aIncludes papillary serous, clear-cell sarcoma.

^bGrade only known for 70 patients.

Overall, 22% of patients with seemingly uterine confined disease were found to have extrauterine spread. Pelvic and/or paraaortic metastases were found in 11% of patients, 12% had positive peritoneal cytology, 5% had adnexal involvement, and 6% had gross intraperitoneal spread. Nodal metastases were related to tumor grade and depth of myometrial invasion, and patients with positive cytology, or adnexal or intraperitoneal spread also had increased frequency of nodal disease.

Patterns of failure in patients with recurrent EC demonstrate, alone or in combination, hematogenous, lymphatic, intraperitoneal, or local/contiguous spread. As attention has increasingly focused on therapies (surgical, radiation, chemotherapy) to reduce particular sites of recurrences, several have argued for defining relationships between initial disease spread and subsequent risk of recurrence (56). In GOG 33, treatment was not specified by protocol, but results showed that outcomes could be predicted by extent of disease found at surgery, thus demonstrating the important relationship between what is learned at surgical staging and recurrence risk (57).

DIAGNOSTIC EVALUATION

Screening

Many ECs develop by way of a precursor lesion. Estrogen-related cancers frequently develop secondary to atypical endometrial hyperplasia (AEH) or demonstrate AEH in the uterus at the time of hysterectomy. Serous tumors also may develop endometrial intraepithelial carcinoma (EIC) through a precursor lesion (58). Prompt recognition of precursor lesions with institution of proper treatment will prevent cancers and their sequelae. The relatively low prevalence of EC in the population (5 per 1,000 women >45 years) makes standardized screening inefficient. There are a few uncontrolled studies lending some support to the efficacy of screening programs (59, 60). No randomized trials have been published. No health economic data have been presented in relation to the published reports. The American College of Obstetrics and Gynecology (ACOG) and the Society of Gynecologic Oncology do not recommend routine screening of patients for uterine cancer (61, 62). The ACS does recommend annual endometrial biopsies starting at age 35 for women known to have or be at risk for HNPCC.

In lieu of routine screening, prompt assessment of symptomatic patients and those at high risk should be considered. Because 95% of endometrial carcinomas occur in women of 40 years old and older, and because endometrial hyperplasia tends to occur in premenopausal and perimenopausal women, it is appropriate to evaluate individuals past their fourth decade of life if there is abnormal bleeding. Similarly, a higher degree of suspicion should be held for younger patients with high-risk characteristics including significant obesity, polycystic ovarian syndrome/chronic anovulation, or tamoxifen exposure.

Prevention

Due to the increased risk of EC associated with unopposed estrogens, women with an intact uterus should rarely, if ever, be prescribed estrogen-only replacement therapy. The addition of progestins to the regimens of patients treated with exogenous estrogen may prevent endometrial hyperplasia and protect against the development of carcinoma (54). Continuous or sequential progestin regimens may be used, but the most important factor is administration of a progestin for at least 10 to 14 days each month. In patients with chronic endogenous estrogen exposure such as obese women with polycystic ovarian syndrome or chronic anovulation, and perimenopausal women

with menometrorrhagia, periodic treatment with a progestin to create scheduled withdrawal bleeding and prevent hyperplasia may be considered (63).

In most cases, patients with hyperplasia with atypia should be treated by vaginal or abdominal hysterectomy to prevent the development of EC (64). Surgery is the definitive therapy as it stops bleeding, prevents cancer, and alleviates the potential of medical failure. Patients with AEH remain at high risk for recurrence of AEH or cancer during their lifetime, even after successful medical therapy (65). Most importantly, despite a preoperative diagnosis of AEH, many patients will be found to have a cancer at the time of hysterectomy (65, 66). Older data suggested that if the endometrial sample is obtained by a biopsy or curettage, 15% to 25% of patients with the diagnosis of atypical hyperplasia may have a uterine carcinoma (67). Prospective data from a large surgical-pathologic trial conducted by the GOG demonstrated that, of 289 patients with a community diagnosis of AEH, 40% had an EC (66). Neither the type of preoperative endometrial biopsy (office endometrial biopsy [EMB], or dilatation and curettage [D&C]) nor the use of an expert pathology panel was associated with a better prediction of who had cancer or not. Patients with significant medical comorbidities, advanced age, or those desiring future fertility may be managed with progestational therapy (68). It has been suggested that a D&C should be performed in those patients who will be medically managed with progestins for therapeutic effect (surgical curettage of tissue) and to better define the risk of an unrecognized cancer, while the data to support these practices are limited. When progestins are used to manage AEH, the specific agents, doses, and schedules may mirror those used to manage dysfunctional uterine bleeding, or advanced or recurrent cancer. To assess the success of medical therapy, endometrial biopsies should be performed at 3- to 4-month intervals provided cancer is not identified (69).

Screening and prevention strategies for women on tamoxifen are more challenging. Women with intact uteri who are taking tamoxifen for either treatment or prevention of breast cancer should be informed of the increased relative risk of developing EC with the use of tamoxifen. This risk is balanced by the reductions in recurrence or development of a contralateral breast cancer. Women on tamoxifen should be encouraged to report abnormal bleeding or vaginal discharge. Screening of asymptomatic women on tamoxifen therapy with ultrasound or endometrial biopsies is not recommended (70, 71).

CLINICAL PRESENTATION

The classic symptom of endometrial carcinoma is abnormal uterine bleeding. A variety of conditions give rise to abnormal bleeding, but particular suspicion should be held for postmenopausal women, and women aged 40 and above with high-risk factors. Approximately 10% of symptomatic postmenopausal patients will be found to have a cancer on biopsy (72). In one series, using age >70 years, diabetes, or nulliparity as risk factors, patients with all three factors had an 87% chance of having an AEH/carcinoma diagnosis, whereas only 3% had significant pathology in the absence of all risk factors (73). Additionally, patients with EC may present with vaginal discharge or have a thickened endometrium incidentally noted on ultrasound performed for another reason. Pap smear screening is not designed to identify EC, but occasionally, patients will have abnormal cervical cytology (atypical glandular cells of undetermined significance [AGUS], adenocarcinoma *in situ* [AIS]). Patients with intraperitoneal disease may present with similar complaints as patients with ovarian cancer such as abdominal distension, pelvic pressure, and pain.

Historically, when EC was a clinically staged disease (FIGO, 1971) fractional D&C was the procedure of choice to evaluate

abnormal bleeding. Fractional D&C permitted assessment of the uterine size and allowed for endocervical curettage, important steps in the staging process. The standard procedure starts with curettage of the endocervix prior to cervical dilatation. Careful sounding of the uterus is performed followed by dilatation of the cervix, followed by systematic curetting of the entire endometrial cavity. Cervical and endometrial specimens should be kept separate and forwarded for pathologic interpretation.

Pathologic evaluation of the endometrium provides histologic diagnosis and can identify other etiologies of bleeding such as chronic endometritis, atrophy, polyps, cervical cancer, or unusual histologic variants (carcinosarcoma, serous carcinoma, placental nodule), which may alter management. Tissue evaluation by office EMB or D&C offer similar information when adequately performed. Today EMB has largely replaced D&C as the diagnostic procedure of choice. In the GOG hyperplasia study, 63% of the specimens were from EMB (Vabra, Novak, Pipelle) and 37% were from D&C (66). Results of endometrial biopsies correlate well with endometrial curettings, and the accuracy to detect cancer is 91% to 99% (74, 75). The accuracy of identifying cancers with EMB is higher in postmenopausal patients than in premenopausal, and a positive study has shown cancer is more accurate for identifying disease than it is in excluding it. Cases where office biopsy cannot be obtained (cervical stenosis, patient intolerance of procedure) or results are nondiagnostic should be followed by D&C. In cases of abnormal bleeding that persists despite negative biopsy, additional investigation is warranted.

Hysteroscopy has been advocated as an adjuvant to D&C to improve detection of pathology in the evaluation of postmenopausal bleeding. Whether it improves the sensitivity to detect hyperplasia and cancers is controversial (76). Hysteroscopy is more accurate in postmenopausal patients, and is more accurate in detecting cancer versus other pathology than it is in identifying cancer or hyperplasia versus other pathology. One concern is that hysteroscopy may promote transtubal migration of tumor cells, which can be detected as malignant pelvic washings on cytology. In one retrospective study, an odds ratio of 3.88 for positive cytology was seen in hysteroscopic D&Cs compared to D&C alone, and the authors cautioned against hysteroscopy to evaluate EC (77). Similarly, a review of literature suggested that water-based hysteroscopy was associated with increased frequency of positive cytology at time of hysterectomy (78). Positive peritoneal cytology as the sole extrauterine factor is no longer recognized as a stage-defining characteristic under the FIGO 2009 system, however (79). No prospective studies have been performed to date, and it remains uncertain what effect positive washing produced by hysteroscopy has, if any, on prognosis.

Ultrasound is commonly used as a less invasive tool to evaluate abnormal bleeding. The measurement of endometrial thickness (ET) has been shown to best predict the absence of carcinoma, with a false-negative rate of 4%, using a threshold value of less than 5 mm (80, 81). The specific ET used for a cutoff value depends on the menopausal status of the patient population evaluated and on the use of HRT. For example, postmenopausal patients on HRT have a median ET 2 to 3 mm more than those not on HRT (82). In a meta-analysis of 85 studies, Smith-Bindman et al. reported that a cutoff level of greater than 5 mm would detect 96% of cancers, and would have a 39% false-positive rate (81). Transvaginal ultrasound measuring the lining thickness of the endometrium has excellent negative predictive value for ruling out ECs or hyperplasia when the thickness is less than 5 mm, but provides less information when greater than 5 mm. Given a pretest probability of having EC in a postmenopausal patient with vaginal bleeding of 10%, a normal endometrial stripe is associated with a 1% chance of a cancer. A consensus panel, composed of radiologists, pathologists, and gynecologic oncologists, suggested that when ET is less than 5

mm, the test can be considered negative for EC (83). For patients with ET greater than 5 mm, EMB, D&C with hysteroscopy, or saline infusion sonohysteroscopy should be performed. Saline infusion sonohysteroscopy has been suggested to better define findings in the endometrial cavity noted on ultrasound and provide clearer distinction of polyps, fibroids, and cancers (84). It is more likely to be successful in premenopausal patients than in postmenopausal patients. The role of vaginal ultrasound in the evaluation of bleeding remains somewhat controversial due to the belief of the importance of histology in defining treatment (for benign and malignant conditions) and of the concern for missed cancers. Good clinical judgment would suggest that patients with ET less than 5 mm who have persistent bleeding undergo tissue biopsy.

DIAGNOSTIC WORKUP

Preoperative Assessment

Following the diagnosis of EC, the surgeon must assess the surgical risks of the patient, evaluate the patient for possible metastatic spread, and determine the most appropriate surgical procedure. EC patients are frequently elderly and suffer from obesity, hypertension, diabetes, or cardiac disease. In a series of 595 consecutive patients, Marziale et al. found an operability rate of 87% (85). Preoperative assessment must be performed, occasionally requiring consultation with additional specialists. At a minimum, patients require a thorough examination to evaluate for evidence of cardiac or pulmonary disease, and to determine the surgical approach. A chest x-ray and electrocardiogram (EKG), complete blood count, and assessment of electrolytes and renal function are standard in this population. Preoperative counseling includes obtaining permission to remove the uterus, tubes, and ovaries, and permission for thorough intra-abdominal exploration with biopsy and tumor removal as necessary, including removal of the pelvic and paraaortic LN.

Evaluation of Metastatic Spread

A thorough physical examination may discover suspicious supraclavicular, inguinal, and/or occasional pelvic LN as well as suggest the presence of pleural effusions, ascites, or omental caking. The pelvic examination can suggest cervical, vaginal, or adnexal spread. An assessment of uterine size and mobility is important, particularly in patients being considered for vaginal approaches (laparoscopic-assisted vaginal hysterectomy [LAVH], total vaginal hysterectomy [TVH]). A chest radiograph is done to search for metastatic tumor as well as to evaluate the cardiopulmonary status of the patient. For patients without obvious extrauterine disease, surgery is the next step. In cases where intra-abdominal, gross cervical, or distant disease spread is suspected, additional studies such as CT scans, magnetic resonance imaging (MRI), or cystoscopy and proctoscopy may be needed to assist with surgical planning.

In general, there is very limited need for imaging studies prior to surgery since findings typically do not result in management changes as most patients present with Stage I–II disease, and the surgery is essentially the same for Stage I–III patients. Imaging studies have significant limitations in detecting nodal disease, which tends to be microscopic in 90% of cases (86, 87). In a small series of higher risk patients who underwent preoperative FDG PET/CT, Signorelli and colleagues showed a 78% patient sensitivity and 93% negative predictive value (88). The GOG is conducting an ongoing prospective assessment of PET/CT in patients with endometrial and cervical cancer (GOG 233). In a prospective blinded comparison of the accuracy of preoperative transvaginal ultrasound to frozen section assessment of

myometrial invasion, intraoperative frozen section outperformed ultrasound. The sensitivity and specificity of predicting invasion (none, <50%, >50%) of the ultrasound was 75% and 89%, respectively (89). Patient review of systems and clinical examination frequently lead to suspicion of gross extrauterine disease. Imaging studies may be of better use in certain situations. Serous and clear-cell tumors have a greater frequency of extrauterine disease spread, and imaging studies may offer additional information in some cases. In some settings, imaging studies may help some to determine whether to refer to a gynecologic oncologist or perform surgical staging when it would not otherwise be considered. In addition, imaging studies may have their greatest utility in helping to counsel young patients who are considering fertility preservation options. MRI has been suggested to have more value than computed tomography (CT) scans in assessing myometrial invasion, cervical invasion, and nodal disease, with several reports indicating a 75% to 90% accuracy rate for determining muscle involvement (90, 91). However, limitations do exist, making routine use more difficult to recommend (92, 93). At the present time, the only way to accurately diagnose the extent and depth of intrauterine invasion is by histologic examination of the hysterectomy specimen.

Biomarkers which predict the presence of extrauterine disease spread might be useful to triage patients to referral centers, for consideration of surgical staging, or to define risk. A variety of biomarkers have been suggested as possible candidates with CA-125 being the most studied (94, 95). Attempts have been made to correlate CA-125 levels with extent of extrauterine disease as serum levels are frequently elevated in patients with advanced or metastatic EC. This observation was first reported by Niloff et al. in 1984 (96). Values exceeding 35 U/mL were found in 14 (78%) of 18 patients with Stage IV or recurrent disease, although none of 11 patients with Stage I disease had elevations. Hsieh et al. reviewed preoperative serum CA-125 levels, operative records, and pathologic reports in 141 patients diagnosed with endometrial carcinoma to find out if the preoperative level of CA-125 can provide additional information to determine the extent of lymphadenectomy required in the surgical staging and which cutoff is optimal in this respect (97). Of 141 patients, 124 were staged surgically and 24 (19%) were found to have lymph node metastasis. In the node-positive group, median preoperative serum levels were 94 U/mL (range 17–363 U/mL). Multivariate analysis showed lymph node metastasis had the most significant effect on the elevation of CA-125 levels (>40 U/mL). The sensitivity and specificity for screening lymph node metastasis were 78% and 84%, respectively. The data of Hsieh et al. give evidence that preoperative CA-125 levels greater than 40 U/mL can be considered an indication for full pelvic and paraaortic lymphadenectomy in the surgical staging of endometrial carcinoma. Rose et al. (98) found serial CA-125 measurements to be most useful in patients with high-risk disease whose initial stage was II, III, or IV, or whose tumor was grade 3 or of clear-cell, or serous histology. Fifteen (94%) of 16 patients with recurrent disease had an elevated CA-125 level. Serial measurements of CA-125 are also used to monitor for recurrence and to assess response to tumor therapy in patients whose levels were initially elevated at diagnosis. In the LACE trial, which compared laparotomy to laparoscopy in the management of early-stage EC, 657 patients had preoperative CA-125 levels, which were correlated with extrauterine disease spread. Using a cutoff of 30 U/mL, 15% were noted to have elevated CA-125 levels, and of these, 37% had intrauterine disease (99). Ideally, serum biomarkers or tests that can be performed on diagnostic samples (EMB, D&C specimens) would be most useful.

Determining the Surgical Procedure

Of all the female pelvic malignancies, EC seems to have more advocates for different treatment plans than any other. The standard

Table 22.3 Corpus Cancer Surgical Staging, FIGO 1988

Stages/Grades	Characteristics
IA G123	Tumor limited to endometrium
IB G123	Invasion to less than half of the myometrium
IC G123	Invasion to less than half of the myometrium
IIA G123	Endocervical glandular involvement only
IIB G123	Cervical stromal invasion
IIIA G123	Tumor invades serosa or adnexae or positive peritoneal cytology
IIIB G123	Vaginal metastases
IIIC G123	Metastases to pelvic or paraaortic lymph nodes
IVA G123	Tumor invades bladder and/or bowel mucosa
IVB	Distant metastases including intra-abdominal and/or inguinal lymph node

treatment for this disease has been and remains a hysterectomy. However, through the years, preoperative and postoperative irradiation has had an important role in the management of this disease. The first significant report of employing irradiation in the management of patients with EC was the publication of the “Stockholm technique” by Heyman in 1935 (100). The use of intracavitary implants using Heyman’s method became increasingly popular in the ensuing years. Subsequently, reports comparing results in patients treated with a single intrauterine tandem with those treated with multiple intrauterine capsules revealed a lower incidence of residual disease and an improved 5-year survival rate, favoring the patients treated with capsules (101, 102). Lewis et al. in cooperative studies in the late 1960s showed that 25% of patients had deep myometrial invasion if treated initially by surgery, and only 8% had deep invasion if treated by preoperative irradiation (103). Patients frequently were managed with preoperative radiation (whole pelvic radiation [WPR], low-dose-rate [LDR] implant with or without WPR) followed within 4 to 6 weeks by a complete hysterectomy. While surgical evaluation of LN in EC was reported in the 1960s, it was not widely embraced (104–106). The GOG undertook the large surgical-pathologic study, GOG 33, of clinical Stage I EC to better define patterns of spread with the hope that defining pathologic relationships would lead to a tailored (rather than a universal) approach to radiation (55, 57). The results of this study subsequently led to the incorporation of a surgical staging system, FIGO 1988 (Table 22.3). In 2009, FIGO updated staging for EC (Table 22.4) (79).

Contemporary management for most patients with EC remains surgical and includes, at the minimum, an initial surgical exploration with collection of peritoneal fluid for cytologic evaluation (intraperitoneal cell washings), through inspection of the abdominal and pelvic cavities with biopsy or excision of any extrauterine lesions suspicious for tumor, and total extrafascial hysterectomy with bilateral salpingo-oophorectomy. In 2009, FIGO removed the status of cytology as a stage-defining criteria (IIIA, by FIGO 1988); however, there was not an intent to discontinue the practice of cytologic evaluation. When the tradition has been to perform this surgery abdominally (typically through a vertical midline incision), minimally invasive techniques have increasingly been integrated into the forefront. The uterus should be particularly observed for tumor breakthrough of the serosal surface. The distal ends of the fallopian tubes are clipped or ligated to prevent possible tumor spill during

Table 22.4 Corpus Cancer Surgical Staging, FIGO 2009

Stages/Grades	Characteristics
IA G123	No or less than half myometrial invasion
IB G123	Invasion equal to or more than half of the myometrium
II G123	Tumor invades the cervical stroma but does not extend beyond the uterus
IIIA G123	Tumor invades serosa of the corpus uteri and/or adnexae
IIIB G123	Vaginal and/or parametrial involvement
IIIC1 G123	Metastases to pelvic lymph nodes
IIIC2 G123	Metastases to paraaortic lymph nodes, with or without positive pelvic nodes
IVA G123	Tumor invades bladder and/or bowel mucosa
IVB	Distant metastases including intra-abdominal and/or inguinal lymph node

Histopathology, Degree of Differentiation

Cases should be grouped by the degree of differentiation of the adenocarcinoma:

G1	5% or less of a nonsquamous or nonmucinous solid growth pattern
G2	6% to 50% of a nonsquamous or nonmucinous solid growth pattern
G3	More than 50% of a nonsquamous or nonmucinous solid growth pattern

Notes on Pathologic Grading

Notable nuclear atypia, inappropriate for the architectural grade, raises the grade of a grade 1 or grade 2 tumor by 1.

In serous adenocarcinomas, clear-cell adenocarcinomas, and squamous cell carcinomas, nuclear grading takes precedence.

Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component.

Rules Related to Staging

Because corpus cancer is now surgically staged, procedures previously used for determination of stages are no longer applicable, such as the finding of fractional D&C to differentiate between stages I and II.

It is appreciated that there may be a small number of patients with corpus cancer who will be treated primarily with radiation therapy. If that is the case, the clinical staging adopted by FIGO in 1971 would still apply, but designation of that staging system would be noted.

Ideally, width of the myometrium should be measured, along with the width of tumor invasion.

D&C, dilatation and curettage; FIGO, International Federation of Gynecology and Obstetrics.

uterine manipulation. To complete the surgical staging of EC, the removal of bilateral pelvic and paraaortic LN is also required.

When surgical staging is performed, a bilateral pelvic and paraaortic nodal lymphadenectomy is frequently performed. The margins of the pelvic nodal dissection are comparable to what is used for a pelvic nodal dissection with cervical cancer and are outlined by the margins of the circumflex iliac vein distally and the bifurcation of the iliac vessels proximally, with the lateral margin being the genitofemoral nerve and the medial

margin being the superior vesical artery. The floor of the dissection is the obturator nerve. Nodal/fatty tissue is skeletonized from these structures. In cases of bulky nodal disease, complete resection/debulking rather than biopsy to solely demonstrate metastatic disease is favored where possible. The common iliac nodes can be removed as a separate specimen, or divided at a midpoint along the vessels, submitting the inferior half with the pelvic nodes, and the superior half with the paraaortic nodes. Particularly on the left side, the common iliac nodes will be quite lateral in location and will require sufficient mobilization to visualize the nodes. Removal of paraaortic nodes can be performed through a midline peritoneal incision over the common iliac arteries and aorta, or by mobilizing the right and left colon medially (107). In each case, LN are resected along the upper common iliac vessels on either side and from the lower portion of the aorta and vena cava. At the present time, the inferior mesenteric artery is used to demarc the superior extent of the paraaortic nodal dissection, although some prefer to routinely extend the dissection to the level of the renal vessels (108). If suspicious nodes extending to the renal vessels are identified, they should be removed if possible.

In cases with gross omental or intraperitoneal disease spread, cytoreductive surgery with total omentectomy, radical peritoneal stripping, and, occasionally, bowel resection are required. The goal of reducing the residual disease to no or small volumes akin to what is performed for ovarian cancer is increasingly considered. In cases complicated by medical comorbidity, advanced age, or obesity, or when nodal dissection cannot or will not be performed, TVH with or without laparoscopic/robotic assistance may also be utilized. Following surgical assessment, patients may be classified based on pathologic features as to their risk of recurrence, and those deemed to be at sufficient risk may be offered adjuvant therapies.

Nonsurgical Management

The principal management of most patients with EC is surgical. The decision to use surgery is a function of patient and disease status. Patients with significant medical comorbidities who are not acceptable candidates for surgery (markedly advanced age, diminished performance status, severe cardiac/pulmonary disease, massive obesity) may be managed by alternative means. Primary radiation therapy without surgery has been used, and is discussed later in this chapter. Progestational therapy may be used for those who are inoperable or in younger patients who elect for fertility preservation (68, 109). Patients not undergoing surgery should be clinically staged according to the clinical staging system proposed by FIGO in 1971 (Table 22.5) (110). Those who do undergo initial hysterectomy are staged by the 2009 FIGO (revised 1988) system (Table 22.4) (79). Patients who are obese but otherwise surgical candidates may undergo an abdominal panniculectomy to enhance surgical exposure to facilitate hysterectomy and nodal dissection (111, 112). For patients presenting with disseminated or nonresectable disease, nonsurgical options including radiation, chemotherapy, or hormonal therapy have also been used. Surgery may be required to control vaginal bleeding in some of these cases.

Approximately 5% of women with EC are diagnosed under the age of 40 (4). For some younger women, the standard treatment of hysterectomy is unacceptable due to desires to maintain fertility. EC in younger women is usually associated with early-stage, low-grade disease and carries a favorable prognosis, making medical management an attractive option to some (69, 109, 113). Patients without myometrial invasion are thought to be the best candidates, and may undergo pelvic MRI to assess for myometrial involvement. Progestational therapy, most commonly with medroxyprogesterone acetate or megestrol acetate, has been successful in reversing malignant changes in up to 76%

Table 22.5 Corpus Cancer Clinical Staging, FIGO 1971

Stage	Characteristics
I	Carcinoma is confined to the corpus
IA	Length of the uterine cavity is 8 cm or less
IB	Length of the uterine cavity is more than 8 cm
<i>Histologic subtypes of adenocarcinoma</i>	
G1	Highly differentiated adenomatous carcinoma
G2	Differentiated adenomatous carcinoma with partly solid areas
G3	Predominantly solid or entirely undifferentiated carcinoma
II	Carcinoma involves the corpus and cervix
III	Carcinoma extends outside the uterus but not outside the true pelvis
IV	Carcinoma extends outside the true pelvis or involves the bladder or rectum

of cases (109, 113). Increasingly, there has been a consideration for progestin-based intrauterine devices, although the data are limited. In a 2012 systematic review of the literature, 74% of AEH and 72% of grade 1 EC patients achieved a pathological complete response (CR) for 6 months or longer with oral progestins (114). The range of complete responses was 50% to 95% for AEH, and 50% to 100% for grade 1 cancer. The mean time required to achieve the CR was 6 months. Of the 22 patients reported with grade 1 cancer treated with IUD, 68% achieved a CR. Because response may be temporary or incomplete, periodic sampling of the endometrium is advised. Penner and colleagues suggested that lack of response to progestin therapy is more common when the first response assessment shows lack of response, despite adjacent stromal decidualization (115).

Vaginal Hysterectomy

Vaginal hysterectomy with or without postoperative radiation may be another option for managing complicated patients. Vaginal hysterectomy has often been cited as the simplest and least morbid approach to hysterectomy, and has produced similar treatment outcomes in patients with clinical Stage I EC (116). It is often used as an alternative to an abdominal approach in obese and poor-surgical-risk patients (117). Limitations include the lack of exploration of the intraperitoneal cavity, inability to procure cytologic washings, greater difficulty in performing an oophorectomy, and inability to perform lymph node sampling. As lymph node metastasis is related to such high-risk features as

poor differentiation, unfavorable histologic subtypes, and deep myometrial invasion, the risk of extrauterine disease following TVH must be estimated based on uterine pathology (55).

Nodal Dissection

The value of staging any malignancy relates to the ability to describe the extent of disease at diagnosis, and to define comparable patient populations for whom prognosis and therapy are similar. Given the inability to accurately detect disease spread for many gynecologic malignancies, solely based on clinical examination and imaging studies, surgical staging systems that require pathologic evaluation of sampled sites have been largely incorporated into practice. The value of surgical staging as it relates to ECs has been the subject of increased scrutiny and debate over the last several years. For ECs, the ability of surgical staging to accurately identify spread to draining lymph node basins and how this information (or lack of it) changes prognosis and alters the use of postoperative therapies are a source of controversy. Proponents of routine surgical staging suggest that the ability to identify otherwise unrecognized disease spread to the nodes changes the postoperative therapies that are given, and is the most accurate way to assess risk. Most controversial is the assertion that surgical staging has a therapeutic benefit independent of the node status (positive or negative for metastatic disease).

Fundamentally, surgeons must determine for themselves whether or not they believe that surgical staging has sufficient value to offer it for all patients or only selectively, based on risk factors identified pre- and intraoperatively. If a patient will not be offered surgical staging/nodal dissection, then minimizing surgical morbidity with a vaginal or minimally invasive (laparoscopic-assisted, robotic) approach seems warranted. In this case, lower risk/quicker recovery comes at the cost of less information. In cases where nodal dissection will or potentially will be performed, patients must be adequately counseled regarding the risks and benefits. The principal risks attributable to nodal dissections include increased operative time, potential for blood loss associated with vascular injury, ileus, genitofemoral nerve injury with resulting numbness and paresthesias over medial thighs, lymphocyst formation, and lymphedema (Table 22.6) (57, 118, 119, 174). In general, the risks associated with nodal dissections are low and acceptable. Patients who have nodal dissections and receive pelvic radiation therapy may be at a greater risk of bowel morbidity than those without dissections (121). Nodal dissections also require the involvement of someone trained and skilled to perform the procedure. The principal advantage of comprehensive staging is that the physician and patient are provided with the greatest amount of information. In the contemporary management of EC, this information results in less use of radiation, and substitution of vaginal cuff brachytherapy (VCB) for pelvic radiation (106, 122, 123).

The importance, extent, and technique of nodal dissection are hotly debated. Questions relate to which patients should be

Table 22.6 Risks Associated with Nodal Dissection: Surgical Complication Rates Associated with Abdominal Hysterectomy + Pelvic and Paraaortic Lymph Node Dissection

Study	N	Hemorrhage (%)	GU injury (%)	DVT/PE (%)	Lymphocyst (%)	Other
Morrow, 1991	895	2.2	0.4	2	1.2	—
Homesley, 1992	196	6% transfused	—	4	—	“Serious” 6%
Orr, 1997	396	4.2% transfused	0.6	1.5	1.2	—
Mariani, 2006	96 node-positive patients	—	1	1	3.1	—

Note: DVT/PE, deep vein thrombosis/pulmonary embolism; GU, genitourinary.

offered and could benefit from surgical staging (all, some, none), and what is the optimal surgical procedure to be performed (biopsy of enlarged/visible nodes, lymphadenectomy). Controversy also exists between those surgeons who perform only pelvic dissections and those who advocate pelvic and paraaortic nodal dissection. If paraaortic nodes are removed, are bilateral nodes required, and to what superior extent (inferior mesenteric artery, renal vessels) should the dissection proceed?

Nodal Dissection—None

In the United States, comprehensive surgical staging of EC is infrequently performed. Only 30% to 40% of patients undergo nodal assessment, indicating that the majority of U.S. patients are not staged (123). Many gynecologists are neither trained in the techniques of lymphadenectomy nor familiar with the concept of full surgical staging. Full staging is more commonly performed by specialized surgeons, such as gynecologic oncologists (124, 125). Philosophically, those opposed to nodal dissections suggest that most patients are at low risk for nodal disease, treatment decisions can be based on final pathologic information, and, despite node dissection, the majority of patients who are node negative do not get benefit (126). Most patients with EC do present with low-risk features. In the entire GOG 33 study population of 621 patients, 75% had grade 1–2 tumors, 59% had inner one-third or less myometrial invasion, and only 9% of patients had positive LN (55). The Postoperative Radiation Therapy in Endometrial Cancer (PORTEC) trial evaluated patients with Stage IC, grade 1; Stage IB–C, grade 2; or Stage IB, grade 3 who underwent hysterectomy without lymph node dissection and compared observation to postoperative pelvic radiation (127). Of note, based on grade and depth of invasion, approximately 60% of patients enrolled in GOG 33 would have had disease characteristics required for eligibility in the PORTEC trial. This patient population managed without nodal dissection had favorable outcomes with or without radiation therapy (5-year survival rates of 85% observation, 81% with pelvic radiation) in the PORTEC study (127). In a follow-up study including 427 patients with higher risk disease (age > 60 years plus either grade 1–2 and outer 50% invasion, or grade 3 with inner 50% invasion, or Stage IIA (1988 FIGO) disease), the PORTEC 2 study compared pelvic radiation therapy to VCB. None of the patients underwent nodal assessment, and 5-year PFS (78% to 83%) and survival (80% to 85%) suggested that even intermediate risk patients may be managed without lymphadenectomy, albeit at the cost of requiring adjuvant therapy, with resulting favorable outcomes (128). Trimble et al. reported on data from Stage I EC patients collected by SEER from 1988 to 1993 and showed that 5-year relative survival for patients without nodal dissection was 98% compared to 96% in those undergoing nodal dissection and suggested that nodal dissection did not convey a benefit for the overall population (129). Unfortunately, data on adjuvant therapy use were not available. It is suspected that increased use of radiation in unstaged patients may produce similar outcomes to patients who are staged and who avoid radiation therapy.

In a nonrandomized trial comparing hysterectomy with or without pelvic lymphadenectomy, followed by radiation therapy, 14% of patients (n = 207) with negative nodes treated with VCB recurred compared to 16% who did not have a lymphadenectomy (n = 660) (130). While the authors noted similar cancer-free survival between the groups, all patients who did not have nodal dissections received both pelvic radiation and VCB to attain these results.

Two randomized trials comparing hysterectomy with or without lymphadenectomy have been reported. A Study in the Treatment of Endometrial Cancer (ASTEC) randomized patients with 1,369 EC to hysterectomy with (LND group) or without (no LND group) pelvic lymphadenectomy (131). Following

surgery, patients with Stage I–IIA disease were then randomized again to observation or pelvic radiation therapy if they had grade 3, serous, or clear-cell histology; greater than 50% myometrial invasion; or endocervical glandular invasion (Stage IIA). Nodal status did not alter the use of radiation therapy such that node positive patients could be assigned to observation. Treatment centers were also permitted to use VCB regardless of pelvic radiation assignment based on institutional preference. As a result, a patient with unknown nodal status could receive VCB and not be considered to have received radiation therapy. Of the LND group, 54 patients were found to be positive nodes (9%) compared with 9 (1.3%) patients in the no-LND group. The quality of the nodal dissection has been criticized in this study as 8% of patients within the LND group did not get a nodal dissection, 12% had less than five nodes removed (median = 12 nodes), and paraaortic nodal dissection was not performed. There was no difference in progression-free survival (PFS) (HR, 1.0) or survival (HR, 1.25; $p = 0.14$) between the LND groups. Pelvic lymphadenectomy was associated with a longer operative time, and increased frequency of ileus (3% vs. 1%), deep venous thrombosis (1% vs. 0.1%), lymphocysts (1% vs. 0.3%), and wound complications (1% vs. 0.3%) compared to the no LND group. The frequency of transfusions and length of hospitalization were comparable between groups. The authors concluded that the results suggest no evidence of benefit for PFS/OS for pelvic lymphadenectomy and that it “could not be recommended as a routine procedure for therapeutic purposes” (131).

A similar study was performed by Italian investigators (CONSORT trial). In this trial, 514 patients were assigned to hysterectomy with or without pelvic lymphadenectomy (132). Patients were required to have myometrial invasion, and patients with grade 1 tumors and less than 50% invasion were excluded. In the no-LND group, 22% of patients had nodal dissections due to clinical suspicion with 14% of these cases, or 3% of the entire no-LND arm, having node positive disease. In the LND group, the median number of nodes removed was 26. Paraaortic dissection could be performed at the surgeon’s discretion and was done in 26% of cases. In the LND group, 13% were found to have positive nodes. Lymphocysts and lymphedema were more common in the LND group, but other early and late complications were similar. Postoperative therapy was not protocol prescribed, but the use of radiation therapy was more common in the no LND group (25% vs. 17%). The 5-year disease-free survival (DFS) was 81% in both groups, and 5-year survival was 90% in the no-LND group versus 86% in the LND group (HR 1.2, $p = 0.5$). The authors concluded that pelvic lymphadenectomy could not be recommended as a routine procedure for therapeutic purposes (132).

Both the ASTEC (A) and Italian (I) studies have been heavily criticized (133–134). Weaknesses of the studies relate to the absence of treatment in patients identified with positive nodes (A), lack of prescribed adjuvant therapy (I), limited power to show improvements in outcome if one truly existed (A,I), poor quality of the LND (A), absence of paraaortic nodal dissection (A,I), lack of quality-of-life assessment evaluating effect of both surgery and downstream use of adjuvant therapy (A,I), and the over representation of low-risk patients (A,I). Despite these limitations, these datasets provide the only level 1 evidence on the role of lymphadenectomy. The studies also suggest that the marginal benefit that lymphadenectomy may provide is likely to be modest for most patients. In addition, the data provide a strong argument that removing negative nodes is unlikely to significantly improve outcomes.

Without nodal information, physicians must rely on uterine factors to estimate the probability for nodal disease and pelvic failure to determine the need for postoperative radiation. Risk assessments may be based on nodal positivity estimates from GOG 33 or based on uterine factor derived risk groups treated with or without radiation therapy (PORTEC, GOG 99)

(55, 121, 127, 135). Nodal positivity is not infrequent in patients with higher risk uterine factors based on GOG 99 or PORTEC models. Nugent and colleagues classified a series of 352 clinical Stage I, endometrioid adenocarcinoma patients into risk groups based on PORTEC and GOG 99 models. Nodal positivity rates were 20% with PORTEC and 35% with GOG 99 H-IR criteria (127). Without specific nodal information, treatments must be based on estimates of risk/probability; this estimation can result in an increase in the use of radiation, particularly if the primary benefit of postoperative radiation is in node-positive patients. Complicating the issue of nodal dissection is that nodal status is only one of several important prognostic factors (136, 137). Kwon and colleagues performed a population-based cohort study of 316 EC patients who underwent lymphadenectomy and reported that pelvic node status was not an independent determinant of survival whereas prognosis was determined more by uterine factors (137).

The absence of nodal dissection may also lead to poorer outcomes. For example, a subset of 99 patients with Stage IC, grade 3 EC, who did not have lymph node dissection, were not eligible, but were treated with pelvic radiation and followed prospectively within the PORTEC trial (138). Five-year survival for this group of patients was 58%, and 12% had vaginal or pelvic failures despite WPR. It is interesting to note that the outcome of this group is poorer than what has been reported in patients with Stage IIIC EC managed by lymphadenectomy followed by radiation (139–141). If patients are not to have nodal dissection, then it would seem reasonable to consider minimally invasive or vaginal approaches to reduce morbidity.

Nodal Dissection—Selective

Surgical staging is the most accurate way to determine the extent of disease spread. Palpation of pelvic LN is not sufficiently accurate, with a sensitivity of 72% in a recent prospective study (142, 143). The baseline rate of nodal disease in an “all comers” population of EC patients is roughly 9% (Table 22.7). Increasingly, the challenge has been how to identify the smaller portion of patients at high risk from the larger low-risk population. Clearly, subgroups of patients at very high risk (nonendometrioid histology, carcinosarcoma, gross cervical involvement, gross intrauterine disease spread) exist, but these represent a minority of the 400,000 cases of uterine cancer per year in the United States. Many gynecologic oncologists consider nodal assessment to be a fundamental step in the evaluation and management of most women with EC, and nodal assessment has been incorporated into the surgical staging of EC since 1988.

Increasingly, there has been a discussion in the literature to attempt to describe which populations should be offered

Table 22.8 Histologic Grade and Depth of Invasion

Depth	Grade, No. of Patients			Total (%)
	Grade 1 (%)	Grade 2 (%)	Grade 3 (%)	
Endometrium only	44 (24)	31 (11)	11 (7)	86 (14)
Superficial	96 (53)	131 (45)	54 (35)	281 (45)
Middle	22 (12)	69 (24)	24 (16)	115 (19)
Deep	18 (10)	57 (20)	64 (42)	139 (22)
Total	180 (100)	288 (100)	153 (100)	621 (100)

lymphadenectomy, and the optimal strategy for defining those at risk (tumor biomarkers, frozen section criteria, sentinel nodal evaluation). Many believe that nodal dissections should be reserved for those with sufficient risk of nodal disease (55, 57, 144, 145). What risk of nodal disease (3%, 5%, 10%, etc.) warrants the procedure is debated—that is, at what level would one be comfortable missing unrecognized nodal spread. Equally important in the discussion is the understanding of whether uterine risk factors, independent of nodal status, should drive risk assessment and use of adjuvant therapy, and whether adjuvant therapies given to those with node positive or node status unknown perform similarly.

Historically, data from GOG 33 demonstrated important relationships between tumor grade and depth of invasion and frequency of nodal disease that can be used to decide whether to perform nodal assessments (Tables 22.8 and 22.9) (55). For example, the risk of pelvic nodal disease was 3% for all patients with grade 1 tumors, but was 11% with deeply invasive (outer one-third myometrial invasion) tumors. Patients with grade 3 tumors had a risk of pelvic nodal metastases of 18%, and 34% with deep invasion. With cervical invasion, the rate of pelvic nodal disease was 16%. Patients with serous or clear-cell histology also warrant nodal dissection as ~30% to 50% will have nodal disease, and even in the absence of myometrial invasion, nodal metastases have been reported in up to 36% of patients (146). Some advocate that LN need not be sampled for tumor limited to the endometrium, regardless of grade, because less than 1% of these patients have disease spread to pelvic or paraaortic LN (55, 147). A gray zone in deciding about lymph node sampling is represented by patients whose only risk factor is inner one-half myometrial invasion, particularly if the grade is 2 or 3. This group has 5% or less chance of node positivity (55). In the most recent survey of SGO members, 35% of respondents reported doing lymphadenectomy for grade 1 tumors; however, the use increased to 60% for grade 2, and 90% for grade 3 (108).

Increasingly, the debate has focused on appropriate selection of patients at such low risk for nodal metastasis that lymphadenectomy may be safely avoided. While flawed, the ASTEC and Italian studies have suggested that routine nodal dissection may have limited value. If the primary value of lymphadenectomy is to identify patients with positive nodes as a “diagnostic test” that defines patients who need additional/different postoperative therapy, there is value in defining populations at sufficiently low risk for whom no lymphadenectomy is required. In 2000, the Mayo group described a model that could classify a group with a low risk of nodal disease spread and high DFS based on frozen section evaluation of the uterus, which showed grade 1 to 2 endometrioid tumor, inner 50% invasion, and tumor size

Table 22.7 Frequency of Nodal Disease

Study	Reference	N	Frequency of Nodal Disease

less than 2 cm (148). Mariani subsequently reported on a prospective experience of 422 patients and reported that 33% of patients with endometrioid type tumors would qualify as low risk in this model. The authors also showed that 22% of patients with risk factors outside of their low-risk model had positive nodal spread at time of lymphadenectomy (149). Several other investigators have attempted to validate these findings. Convery and colleagues tried to replicate the conditions of Mayo criteria (which are assessed intra-operatively by frozen section) by retrospectively evaluating 602 patients with grade 1–2 endometrioid EC and who had intra-operative assessment of tumor (for depth of invasion ± tumor size) (150). The authors showed that 2/110 (1.8%) patients meeting the Mayo criteria who underwent a lymphadenectomy removing at least eight nodes were found to have metastatic spread to LN. Milam attempted to validate the Mayo criteria using a 971-patient surgical dataset from patients participating in the GOG Lap 2 trial (randomized trial of laparoscopy vs. open hysterectomy with pelvic and para-aortic lymphadenectomy (151). Of 971 patients with endometrioid adenocarcinoma and complete data, 65 (7%) were identified

with positive LN. Patients were classified into a “low risk” category based on 3 Mayo criteria; grade 1–2 tumor, less than 50% myometrial invasion, and tumor size less than 2 cm. These risk characteristics were assigned based on final pathology report and not frozen section, however as was used in the Mayo studies. Approximately 40% of patients met the low-risk criteria, and of these, 3/389 (0.8%) had positive LN.

Kang, reporting for the Korean GOG, retrospectively evaluated 540 patients with endometrioid-type cancers who had undergone preoperative EMB, CA-125 level, and MRI followed by hysterectomy and pelvic lymphadenectomy to create a risk model for predicting nodal disease (152). The model was developed on a 360-patient training set and validated against a 180-patient cohort. Interestingly, the logistic regression model included only data from the MRI and CA-125 level; grade was not an independently significant variable. The authors suggested that based on preoperative information, they could classify 53% of patients as low risk (<50% myometrial invasion and absence of enlarged nodes or extrauterine disease by MRI and CA-125 < 35 IU/ml). Of the low-risk group, only one patient had positive nodal disease (1.7% false-negative rate) suggesting that these patients may avoid an unnecessary lymphadenectomy.

Low-grade tumors appear to be the best population for developing criteria to limit lymphadenectomy. Bernardini performed a retrospective comparison between two academic institutions’ preferences for management of preoperative grade 1 endometrioid EC (153). Of 483 cases with a preoperative grade 1 cancer, final pathology was grade 1 in 357/483 (74%) cases, and 20% were upgraded (grade 2, 18%; grade 3, 2%). In one institution, surgical staging was performed in 50% of cases, and four (3%) patients were identified with nodal disease. At the second institution, lymph node dissection was performed in only 12% of patients, and three (1.4%) were found to have positive nodal disease. At the second institution, postoperative use of radiation therapy was more common (21% vs. 7%), although older patient age, capillary space invasion, and cervical involvement were more common at the second site. Despite the differences in surgical practice, the 3-year survival was 96% at both centers. These data indicate that there is little margin to improve outcomes through strategies directed at all patients in this patient population.

Selective use of nodal dissection highlights the balance between the likelihood of identifying otherwise unrecognized disease against cost, morbidity, and use of adjuvant therapy (with downstream cost, morbidity). The overall surgical complication of lymphadenectomy is approximately 20%. The serious complication rate is ≤6%, and is likely to be lower with surgeons who more frequently perform the procedure (57, 118–120). Downstream utilization of adjuvant therapy, which may occur more frequently in the absence of lymphadenectomy, must also be considered into this balance. While the proposed models predicting low-risk disease status appear to be accurate, it is important to understand that the pre-test probability of having positive nodes in a large patient population with grade 1 to 2 endometrioid tumors is ~3% to 7%, illustrating the narrow margin in improved outcome (e.g., identify 100% of patients with positive nodes and then use adjuvant therapy which cures 100% of these) that lymphadenectomy may be able to offer in this population of patients. Lymphadenectomy perhaps allows for fine tuning the management of low-risk patients, but does not appear to be the driver of outcomes.

Intraoperative assessment of the uterus has been used to guide the surgeon as to when to perform a nodal dissection. Gross inspection of the uterus immediately following its removal can be used to estimate the degree of myometrial invasion. If the uterus is opened by the operating surgeon, care should be employed to avoid distortion of the anatomy. Optimally, the unfixed uterus should be opened by the surgical pathologist, who can grossly estimate the depth of invasion, assess involvement of the cervix, and later sample the tumor for histologic assessment. There is

FIGURE 22.1. Endometrioid adenocarcinoma. A polypoid adenocarcinoma of the endometrium that fills much of the lumen and superficially invades the myometrium.

no typical gross appearance of an endometrial carcinoma. Most are polypoid or ulcerative. Carcinoma usually differs in texture and color from the surrounding normal endometrium. The normal endometrium is irregular and tan, but a carcinoma is usually shaggy, white to gray-white, and focally hemorrhagic. Areas of myometrial invasion may be visible as gray-white to white, with yellow areas disclosing necrosis (Figs. 22.1 and 22.2). The texture may be soft, friable, or firm depending on the degree of necrosis.

Doering et al. reported a 91% accuracy rate for 148 patients for determining the depth of myometrial invasion by gross visual examination of the cut uterine surface (154). A prospective study indicated that visual inspection of less than or greater than 50% correlated with microscopic assessment in 85% of cases (143). However, the sensitivity of determining greater than 50% was lower at 72%. Invasion of the myometrium may be more extensive microscopically than is evident visibly because of the characteristic infiltrative growth pattern of the tumor. In a retrospective study by Goff and Riche, the gross estimation by pathologists of myometrial invasion in grades 2 and 3 tumors was poor (155). With invasion, the uterine cavity usually enlarges and the myometrium thickens, but a small uterus may have myometrial penetration to the serosa.

Nodal Dissection—Routine

Data from 1990 to 2000s provided support for performing uniform comprehensive surgical staging for nearly all patients

FIGURE 22.2. Endometrial adenocarcinoma. An ulcerating and deeply invasive adenocarcinoma that extends into the uterine cervix.

with EC. The rationale for uniform staging includes the lack of a patient population for whom nodal disease is so low that nodes should be omitted, the inaccuracy of preoperative or intraoperative assessments predicting the risk for nodal disease, the potential for therapeutic benefit in node-positive and -negative patients, and the lack of significant morbidity associated with the procedure. Postoperative adjuvant decisions are best made with the most complete information. If nodal assessment is the predominant factor by which to categorize patients into risk groups, routine nodal dissection is the best method by which to determine which few patients will require adjuvant therapy.

What constitutes an acceptable rate of nodal disease in EC to warrant the procedure is surgeon dependent. In cervical cancer, routine pelvic lymphadenectomy is advocated for all Stage IA2 tumors where nodal positivity rates are 3% to 5%. For clinical Stage I ovarian cancer, paraaortic dissection is recommended for all given the 6% risk of paraaortic disease. In EC, major complication rates associated with nodal dissection are 2% to 6%, suggesting that this might be an appropriate level of risk to balance against the risk of nodal metastases. Data from GOG 33 show that only patients with tumor limited to the endometrium had a risk of pelvic nodal disease $\leq 3\%$, and this group accounted for only 14% of the entire study population.

Frozen section assessment has been the traditional tool to facilitate decisions on selective nodal dissections. Several studies have demonstrated inaccuracies with frozen sections in the interpretation of grade and depth of myometrial invasion compared to final pathology (156, 157). In one prospective evaluation, frozen section determination of depth of invasion correlated with final pathology in 67% of cases but resulted in upstaging in 28% of cases (156). Patients with grade 1 EC or AEH were upstaged in 61% of cases. The clinical significance of these errors has been debated (126), but many believe that such unexpected up-staging justifies routine staging even in seemingly low-risk patients (156, 157). Data also suggest that the strategy of routine nodal dissection is more cost effective than either no staging or selective staging based on frozen section results (158).

The technique of nodal dissection has undergone evolution. In an era where everyone was to receive radiation therapy, there was little value for a complete evaluation of LN. Removal of palpably enlarged nodes, “plucking” of visibly noted nodes, and “sampling” have given way to a more thorough assessment. Only 10% of patients with metastases to LN will have grossly enlarged nodes and frequently, even in these cases, direct palpation through the overlying peritoneum will fail to identify them (55). Today, adjuvant therapies are based on the extent of disease, and are often only reserved for node-positive patients. Nodal assessments should sufficiently examine sites at risk, including external iliac, hypogastric, and obturator nodes in the pelvis, common iliac nodes, and paraaortic nodes. Moving from a sampling technique to a more thorough lymphadenectomy is not associated with increased complication rates (159). Nodal dissection should be bilateral given the frequency of both left and right paraaortic involvement (160, 161). It is interesting to note that GOG 33 only specified right-sided paraaortic removal in the surgical protocol. Likewise, the nodal dissection is more apt to be representative when a larger number of nodes are removed.

An assessment of pelvic and paraaortic LN is required to assign stage according to FIGO 2009. The 2009 staging system now separates stage subcategories based on extent of nodal disease (IIIC1, pelvic positive, IIIC2, any paraaortic positive) (79). Two principal nodal basins drain the uterus: the lower and middle portion of the uterus drains laterally to the pelvic LN; the upper corpus and fundus drain to the paraaortic nodes. When LN are positive, paraaortic nodes are involved in ~50% of the time. Isolated paraaortic nodes with negative pelvic nodes are uncommon, particularly with grade 1–2 tumors, and are involved in only ~2% of cases (55, 162). Paraaortic nodal

Table 22.10 Relationship between Pelvic and Paraaortic Nodal Involvement in Patients with Node-Positive Endometrial Cancer

Study	N	Surgical Technique	Pelvic (+) Only (%)	Pelvic and Para-aortic (+) (%)	Para-aortic Only (%)	Any Involvement of Para-aortic Nodes (%)
Creasman (1987) (162a)	70	Routine: sampling	51	31	17	48
Schorge (1996)	35	Selective: lymphadenectomy	74	17	9	26
Hirahatake (1997)	42	Routine: systematic lymphadenectomy	57	38	5	42
Onda (1997)	30	Routine: systematic lymphadenectomy	33	60	6.6	66
McMeekin (2001)	47	Routine: lymphadenectomy	38	41	21	62
Otsuka (2002) (162b)	23	Selective: systematic lymphadenectomy	66	33	10	43
Havrilesky (2005)	96	Selective: lymphadenectomy	52	30	18	48

dissection is more difficult to perform than pelvic dissection, by laparotomy or by laparoscopy, and is associated with greater risk. As such, some advocate for pelvic nodal dissections with only selective performance of paraaortic nodal dissections. In GOG 33, 46% of the positive paraaortic LN were enlarged, and 98% of the cases with aortic node metastases came from patients with positive pelvic nodes, adnexal or intra-abdominal metastases, or outer one-third myometrial invasion (55). These risk factors affected only 25% of the patients, yet they yielded most of the positive paraaortic node patients.

The importance of paraaortic nodal spread in node-positive EC cannot be ignored (Table 22.10). Data from GOG 33 showing that of all patients, isolated paraaortic nodal metastases occurred in 2%, are often taken out of context (55). If the goal of nodal dissection is to identify the node-positive patient population and to remove involved nodes, paraaortic disease is seen in 40% to 66% of patients with node-positive/Stage IIIC1/2 EC, including isolated positive paraaortic nodes in up to 7% to 21% of cases in certain groups. If only pelvic nodes are removed, when they are positive, paraaortic nodes will be positive in addition in nearly 30% to 40% of cases. It makes less sense to remove only pelvic or only paraaortic nodes given this data. Data would also suggest that when positive, outcomes are improved in patients who have complete surgical resection of paraaortic nodes. Chuang et al. reported on their experience with selective pelvic and or paraaortic dissections and found that failure to systematically remove pelvic and paraaortic nodes resulted in an increased frequency of recurrence in undissected retroperitoneal sites (163). Similarly, Mariani et al. showed that patients at high risk for paraaortic nodal disease (based on invasion >50%, palpable positive pelvic nodes, positive adnexa) who did not have paraaortic dissection or who had biopsy only and who were managed as though paraaortic nodes were positive had 5-year survival of 71% compared to 85% for those patients with positive paraaortic nodes who did undergo complete resection (159). Lymph node recurrences were detected in 37% of those not having paraaortic dissection compared to none in patients with positive but resected paraaortic nodes, suggesting a possible therapeutic effect of removing involved paraaortic nodes.

A provocative study from Japan (SEPAL study) was published in early 2010 which retrospectively compared the practices of two centers with regards to use of pelvic with or without paraaortic lymphadenectomy (164). At one center, systematic pelvic lymphadenectomy was performed in 325 patients. With a median of 34 pelvic nodes removed, the incidence of Stage IIIC disease was 12%. At the second institution, 346 patients underwent pelvic and paraaortic lymphadenectomy. With a median of 59 pelvic and 23 paraaortic nodes resected, Stage IIIC disease was identified in 16%. The centers were well matched

for stage and tumor grade, but the center where paraaortic lymphadenectomy was performed used adjuvant chemotherapy more commonly (47% vs. 27%). Patients were classified into low-versus-intermediate to high-risk groups, and outcomes were compared based on lymphadenectomy type. In the intermediate-high-risk group (but not low risk), recurrence-free, disease specific, and OS were significantly better in those women receiving paraaortic dissections. In a multivariate analysis, age, tumor type, nodal spread, and type of lymphadenectomy were independently associated with improved survival. The authors suggested that if future lymphadenectomy trials were to be conducted, both pelvic and paraaortic lymphadenectomy should be performed (164).

At the present time, the superior extent of paraaortic dissection should be at least to the level of the inferior mesenteric artery. Some suggest that dissections should proceed to the level of the renal vessels given the venous and lymphatic drainage following the infundibulopelvic ligament. In one series, 7 out of 11 patients had positive paraaortic nodes identified above the inferior mesenteric artery (165). The Mayo group noted that when paraaortic nodes were positive, 77% of cases had involvement above the IMA (149). This extended paraaortic dissection is feasible laparoscopically as well (166, 167). Prospective data describing the frequency of high paraaortic/pararenal nodes are awaited.

The retrospective data suggesting a therapeutic benefit supports but does not prove the hypothesis that lymphadenectomy is therapeutic. These studies are largely from single institutions, have short follow-up, suffer from selection biases, and do not clearly account for stage migration. Despite these limitations, the therapeutic value of lymphadenectomy is supported by several reports. Kilgore et al. were among the first to report a therapeutic effect of nodal dissections in a series of 649 clinical Stage I-occult II patients who were classified based on the extent of nodal dissection (168). Patients who underwent multiple site pelvic nodal dissection (defined by nodal dissection of at least four pelvic nodal sites) and had a mean of 11 nodes removed had improved survival over those patients who did not have nodes sampled. The survival advantage for multiple site dissection persisted even when patients were stratified into low-risk (uterine-confined disease) and high-risk (extrauterine disease) groups who received radiation. An explanation for this may be the removal of unrecognized micrometastasis, which goes undetected by standard pathologic processing techniques. Girardi et al. performed pelvic lymphadenectomy in 76 patients with EC (169). Nodal tissue was processed as step serial sections, and 37% of positive nodes were less than 2 mm in diameter, suggesting that nodal metastases may be missed in a proportion of node-positive patients processed in a less-extensive manner. Others have shown improvement in outcomes following a

more complete nodal dissection in node-negative populations. Cragan et al. evaluated 509 Stage I–IIA patients who underwent selective pelvic +/- paraaortic lymphadenectomy and found a survival advantage for patients with grade 3 tumors who had greater than 11 pelvic nodes removed, compared to those with ≤ 11 nodes removed (HR, 0.25) (170). For patients with high-risk features (grade 3, $>50\%$ myometrial invasion, serous/clear-cell tumors) 5-year survival was 82% when greater than 11 nodes were removed versus 64% when ≤ 11 nodes were removed. Chan et al. reported on the effect of a more complete nodal dissection in over 12,000 women with EC tracked in the SEER data system. In patients with high-risk disease (IB/grade 3, IC, II–IV), 5-year survival was proportional to the number of nodes removed, increasing from 75% to 87% when 1 versus >20 nodes were removed (171). In a multivariate analysis, a more extensive nodal assessment was an independent predictor of survival. Prospective data from the ASTEC and Italian studies suggest that there is no therapeutic benefit to resecting negative LN (131, 132). The use of postoperative adjuvant therapy in patients without nodal dissection may obscure potential benefit of lymphadenectomy, making benefit difficult to measure. Likewise, patients with low-risk uterine factors may be identified with nodal disease.

In patients with positive pelvic and/or paraaortic nodes, complete resection followed by adjuvant therapy results in superior outcomes. Havrilesky reported on 91 patients with Stage IIIC disease, including 39 with microscopic involvement of the LN and 52 with grossly enlarged nodes. Five-year survival was 58% for patients with microscopic LN, 48% for those with grossly positive LN completely resected, and only 22% in cases where the nodes were not resected. The authors felt that this data suggested a therapeutic benefit for lymphadenectomy (172). Bristow et al. evaluated 41 patients with bulky adenopathy who underwent complete resection of involved nodes. Compared with patients who had gross residual disease in LN remaining after surgery, those with resected disease had longer PFS (38 vs. 9 months) (173). Mariani et al. showed that pelvic sidewall failure at 5 years was 57% for patients who had inadequate nodal dissection and/or no adjuvant radiation compared to 10% when patients had adequate (removal >10 nodes) lymphadenectomy and received radiation (174). The best outcomes reported for node-positive patients follow complete nodal dissection. For example, in one series, of 30 Stage IIIC patients managed with systematic pelvic and paraaortic lymphadenectomy (average number nodes removed, 66) followed by radiation therapy and chemotherapy, 5-year survival was 100% for patients with positive pelvic nodes and 75% for positive paraaortic nodes (139).

The most cogent argument for routine staging is that following thorough nodal assessment, most patients with node-negative disease can accurately be classified as low risk, and may avoid pelvic radiation or receive VCB in lieu of pelvic radiation therapy. Three randomized trials comparing radiation to observation have failed to demonstrate a survival advantage for adjuvant pelvic radiation therapy in patients with Stage I–II disease, suggesting that in the absence of nodal disease, no therapy is a reasonable option (121, 127, 175). Indeed, patients with negative nodes and low-risk uterine factors (which account for 2/3 of Stage I–II EC patients) have incredibly low risk of recurrence and death (2% cancer specific death at 48 months, with or without pelvic radiation) (121). Retrospective studies have shown how the incorporation of a strategy using lymphadenectomy changes the use of postoperative radiation (106, 118, 122, 176). In a SEER review of 26,043 women with EC, patients with intermediate-risk disease who underwent nodal assessment were less likely to receive external beam pelvic radiation therapy and more likely to receive vaginal brachytherapy compared to women who did not undergo nodal assessment (123). In the absence of nodal disease, recurrence risk is low and OS is high, with no radiation or with the substitution of VCB.

Alternatives to Lymphadenectomy

Given the debate as to the value of lymphadenectomy, a variety of alternative strategies have been evaluated. The concept of lymphatic mapping by sentinel lymph node dissection has been accepted into practice in patients with breast cancer and melanoma, and is increasingly being used in vulvar cancers. The technique uses a preoperative local injection of radioactive colloid 6–12 hours preoperatively followed by a lymphoscintigram, with or without an immediately preoperative injection of a colorimetric dye (isosulfan blue). The theory suggests that regional nodal spread first moves to a “sentinel” node(s) for which markers (lymphoscintigram, gamma counter, gross blue appearance of node) make apparent. By selectively resecting the sentinel node, the “at risk node” is evaluated, but other nodes are retained *in situ*, thus reducing morbidity, length of surgery, and blood loss. For sentinel mapping to be effective, reproducible techniques must be developed and validated, standard nodal processing (serial sectioning, immunohistochemical evaluations) must be developed, and the false-negative rate must be low. Given the pretest probability for nodal disease is low ($\sim 9\%$) in an all-comer population, large studies will be required to adequately evaluate sentinel node mapping.

The appropriate site of injection for colloid/blue dye is evident in vulvar cancers and cutaneous melanomas; however, there is debate on where to inject the uterus to be representative of nodal drainage of the tumor. Possible sites of injection include the uterine fundus, cervix, or hysteroscopic injection of the tumor (177). As lymphatic drainage of the uterus is complex, it is unclear whether injections of the cervix mirror drainage of the uterus in general, or specifically of the tumor. For example, there is discussion in the literature as to whether cervical injections may identify paraaortic sentinel nodal disease. In addition to the surgical technique, controversy exists as to the best way to process sentinel node specimens. Immunohistochemical processing searching for cytokeratin is important in that it increases the detection of micro-metastatic implants, although the clinical significance of this type of disease is uncertain (178, 179).

Investigators at Memorial Sloan-Kettering Cancer Center have performed a series of sentinel node mapping surgeries on 266 patients, followed by pelvic $\pm$ paraaortic lymphadenectomy. Using a cervical injection technique, they reported sentinel detection was possible in 84% of cases, 12% of cases had positive nodal disease, and metastatic cells were three times more likely in sentinel nodes than in nonsentinel nodes (180). In a meta-analysis of 26 series on sentinel node dissection, Kang estimated the detection rate for sentinel nodes was 78%, and the sensitivity was 93%. In a disease where baseline rates of nodal involvement are roughly 10%, this translates to a $\sim 1\%$ false-negative rate (181). As most of the series in the meta-analysis included small numbers of patients, the authors cautioned against routine substitution of sentinel nodal mapping for lymphadenectomy based on the current data.

Minimally Invasive Surgery for Endometrial Cancer

After several years of debate and discussion, minimally invasive techniques have been integrated into the management of EC as a standard of care. Techniques utilized in the initial treatment of EC include laparoscopic assisted vaginal hysterectomy (LAVH), total laparoscopic hysterectomy (TLH), and robotic hysterectomy with pelvic and paraaortic nodal dissection to stage patients. Minimally invasive staging techniques include transperitoneal and extraperitoneal assessment of nodes, and may be done at the time of hysterectomy or at a later time to re-stage patients following incomplete surgical staging. The decade of the 1990s advanced the use of minimally invasive surgery and introduced the laparoscopic techniques and tools required for comprehensive

surgical staging of EC. As the initial debate on LAVH focused on whether laparoscopic techniques could be substituted for abdominal ones, in EC, debate has focused on whether laparoscopic surgical staging could be substituted for open procedures. Initial case reports and small single-institutional series describing technique and demonstrating feasibility were replaced by large series, small randomized trials, and subsequently, multi-institutional randomized controlled trials (182–187).

Improvements in laparoscopic equipment facilitated the development of LAVH. Building on that experience, and coupled with the introduction of better optics for visualization, laparoscopic resection of LN became possible. Querleu et al. were the first to report pelvic lymphadenectomy for cervical cancer in 1991 (188), followed by Nezhat et al. who reported in 1992 on the use of laparoscopic pelvic and paraaortic lymphadenectomy with radical hysterectomy in cervical cancer (189). When first utilized in EC, laparoscopic paraaortic node dissection only evaluated right-sided nodes (182). Techniques have subsequently been developed allowing for dissection to include the left paraaortic nodes and for extraperitoneal approaches (166, 167, 190).

Childers et al. (182, 183) described the initial experience of LAVH in 59 patients with clinical Stage I endometrial carcinoma. Laparoscopic pelvic and right-sided aortic lymph node samplings were performed in patients with grade 2 or 3 lesions, or with grade 1 lesions and greater than 50% myometrial invasion on frozen section. For the group, the mean weight was 153 pounds, and in two patients, laparoscopic lymphadenectomy was precluded by obesity. Six patients had the procedure converted to open due to intraperitoneal disease, and two patients required laparotomy to manage complications, including a transected ureter and a cystotomy. The mean hospital stay was 2.9 days. Since that time, many retrospective series have appeared in the literature describing techniques and presumed advantages. In general, mean operating times are longer for laparoscopy, but the overall complication rates, length of stay, and hospital charges were lower. With short follow-up, there was no significant difference in disease recurrence between the two groups.

Prospective data have also emerged. A small prospective, randomized trial comparing laparoscopic-assisted vaginal versus abdominal surgery in patients with EC was reported by Malur et al. (184). They randomized 70 patients with EC FIGO Stage I–III to laparoscopy-assisted simple or radical vaginal hysterectomy, or simple or radical abdominal hysterectomy with or without lymph node resection. Blood loss and transfusion rates were significantly lower in the laparoscopic group. The number of pelvic and paraaortic LN, duration of surgery, and incidence of postoperative complications were similar for both groups. No significant differences in disease recurrence rate and long-term survival were found between the laparoscopic and laparotomy groups (97.3% vs. 93.3% and 83.9% vs. 90.9%, respectively). Malzoni and colleagues reported on a 159-patient trial comparing TLH to TAH with lymphadenectomy (191). The authors reported less blood loss, shorter hospitalization, and less common ileus with TLH. Operative time was longer (136 vs. 123 minutes) with TLH, but there was no difference in number of nodes removed, frequency of Stage IIIC disease, ability to do paraaortic dissection, or in recurrence. The LACE trial compared TLH (n = 190) to TAH (n = 142) in 332 patients with Stage I EC (with or without lymphadenectomy) (187). The preliminary report designed to specifically assess quality of life endpoints showed that 2.4% of laparoscopic cases required conversion to an open approach, operating time for TLH on average was 30 minutes longer, grade 3–4 adverse events were more frequent (23% vs. 12%) in the TAH groups, and quality of life assessments favored TLH for up to 6 months post surgery. Concurrent lymph node assessment was more common with TAH versus TLH (68% vs. 41%), and ~20% of patients participating in the

study received some form of adjuvant therapy (chemotherapy, radiation, or both).

The largest and most comprehensive data set to date comes from the large prospective, randomized trial conducted by the GOG (Lap II trial) (186). The study was designed to compare laparoscopic hysterectomy with comprehensive surgical staging to the traditional laparotomy technique (using a 2:1 randomization favoring the laparoscopic arm) to determine the complete staging rates, safety, short-term surgical outcomes, and long-term cancer recurrence and survival. The study enrolled 920 patients to the open arm, and 1,696 to laparoscopy. The rate of conversion from laparoscopy to open procedure was 26%, and was most frequently related to poor visibility (15%), extrauterine cancer spread (4%), and bleeding (3%). The conversion rate increased with increasing patient obesity, with the laparoscopic success rate being 90% with a body mass index (BMI) less than 20, 65% with BMI = 35, and 34% with BMI = 50. The median number of removed nodes was similar between each technique, as were the frequencies of patients found to have positive LN. Complication rates (combined rates of vascular, urinary, bowel, nerve, or other complications) for those who had an open procedure were 7.6%, compared to 9.5% of patients randomized to laparoscopy. Of the 1,242 patients randomized to laparoscopy who had the procedure successfully completed laparoscopically, the complication rate was 4.9%. Comparing patients who underwent open surgery versus successful completion of laparoscopy, operative time was longer (median 70 minutes), but hospital time was shorter (2 vs. 4 days) with laparoscopy. Postoperative arrhythmia, pneumonia, ileus, antibiotic use, and any complication greater than grade 2 were lower in the laparoscopic group. The authors concluded that laparoscopic surgical staging is an acceptable and possibly a better option, particularly when the surgery can be successfully completed laparoscopically.

Results of long-term survival in laparoscopically treated compared to laparotomy-treated EC patients suggest comparable outcomes. Tozzi, reporting on the first prospective trial (n = 122 patients), reported DFS of 91% with LAVH and 94% with laparotomy, with survival of 86% versus 90%, respectively (192). In a subsequent evaluation of recurrence and survival data from the GOG LAP 2 trial published in 2012, 3-year recurrence rates were 11.4% with laparoscopy versus 10.2% with open surgery, and 5-year survival was 90% in each arm (193).

Age and obesity have been suggested as relative contraindications to laparoscopic surgery. In the GOG Lap II trial, the median age was 63 years. Scribner et al. evaluated the surgical experience of uterine cancer patients age ≥65 years who underwent LAVH with pelvic and paraaortic lymphadenectomy (n = 67) or abdominal hysterectomy with pelvic and paraaortic lymphadenectomy (n = 45) (194). Laparoscopic staging could be completed in 78% of patients. In the laparoscopic group, the BMI was 29.5 kg/m² (range, 15.9–54.7), and 33% had a history of prior laparotomy. For the 22% of patients who required a conversion to laparotomy, obesity (10%), bleeding (6%), and intraperitoneal disease (5%) were the most frequent reasons. Similar nodal counts (29 laparoscopy, 29 open) were noted, the operative time was longer (236 vs. 148 minutes), and hospital stay was shorter (median 3 vs. 5.6 days) with laparoscopy. The authors concluded that with the anticipated growth of an aging patient population, laparoscopic management is a viable option.

Obese patients have been suggested to be poor laparoscopic candidates due to difficulties in establishing pneumoperitoneum, poorer visualization, inability to tolerate steep Trendelenburg positioning needed to facilitate the surgery, and difficulties with ventilation. In the report by Childers et al. mean patient weight was only 153 pounds (182, 183). It is important to recognize that regardless of surgical approach, complete surgical staging is more difficult in an obese patient. Scriber et al. compared 55 obese patients (median weight 96.6 kg, median BMI 40) who underwent LAVH with pelvic and paraaortic lymphadenectomy

to 45 patients (median weight 101 kg, median BMI 39) who had abdominal hysterectomy with pelvic and paraaortic lymphadenectomy (195). Successful completion of laparoscopy was possible in 64%, with patients with a BMI <35 kg/m² having an 82% success rate compared to 44% when the BMI was greater than 35 kg/m². Eltabbakh et al. evaluated 40 women with BMI between 28 and 60 who were treated with LAVH and compared them to 40 similar women treated by abdominal approach (196). Laparoscopic conversion was only required in 8% of patients. Laparoscopic surgery was associated with a longer operative time (195 vs. 138 minutes), but more pelvic nodes (mean 11 vs. 5), less pain medicine requirement, and shorter hospital stay (2.5 vs. 5.6 days) were recorded. Total laparoscopic hysterectomy has also been shown to be feasible in heavier patients (197). In the prospective GOG series, there was ≥80% success rate with patients with a BMI of 27 or less, but even at a BMI of 35, 65% could have successful laparoscopic surgery (186).

Robotic surgery may represent the next step forward in minimally invasive surgery. Since FDA approval for hysterectomy and myomectomy procedures in 2005, there has been an increasing utilization of robotic surgery within Gyn-oncology. To date, greater than 15 series ranging in size from 4 to 405 patients have described robotic experience or compared outcomes to laparoscopy and/or open procedures (Table 22.11) (198–207, 212). Proposed robotic surgery advantages include improved visualization with 3-D optics, “wrist-like” motion of instruments allowing greater dexterity, reduction in tremor, an easier learning curve for adoption compared to straight-stick laparoscopy, and more comfortable ergonomics. Published data suggest comparable outcomes with respect to blood loss, nodal counts, and operative time compared to laparoscopy. Mean nodal counts and operative complications are comparable to laparoscopy, with several series suggesting lower postoperative complications compared to open surgery. As with new surgical techniques, there is a learning curve through which additional experience leads to quicker operative times and higher nodal retrieval rates. The Ohio State group has suggested that 20 procedures are required for proficiency (205).

Robotic surgery may offer unique opportunities for obese patients (206). Several series suggest that robotics may overcome some of the challenges with laparoscopy and may reduce morbidity seen with open cases. Seamon and colleagues reported that in a series of 109 obese patients (mean BMI 40) treated by robotic hysterectomy and staging, the conversion rate was 16%. The 92 patients successfully treated by robotic platform were compared to a matched cohort of 162 laparotomy patients. Total nodal counts (~24 nodes each group) and frequency of adequate lymphadenectomy (defined as at least 10 nodes removed) were similar in both groups, but blood transfusion rate, hospital stay

complications, and wound problems were reduced with robotic surgery.

Arguments have been advanced for and against each of the surgical approaches to EC. Vaginal hysterectomy was once a favored operation, but it did not allow for routine removal of the ovaries in some patients, permit inspection of the peritoneal cavity or the retroperitoneum for metastatic disease, or allow collection of peritoneal fluid for cytology (207). Laparoscopic-assisted or total laparoscopic approaches overcome these limitations, however. Compared to open procedures, LAVH/TLH are thought to lead to reduced incisional complications, wound infections, ileus, hospital stay, cost, and improved rate of recovery and quality of life (186, 188, 208). Data from prospective studies also showed that short-term (6 weeks–6 months) patient-assessed quality of life assessments also favor minimally invasive surgery (208). In patients requiring postoperative radiation, laparoscopic surgical staging followed by radiation therapy is suggested to result in fewer bowel adhesions and radiation-induced bowel injuries. Criticisms of LAVH/TLH with laparoscopic nodal dissection relate to the learning curve required to learn new or unfamiliar procedures, the increased length of operative times, and concerns about the adequacy of the nodal dissection. Studies do suggest that with increased experience, operative times decrease and nodal counts increase. Laparoscopy also introduced different procedural-related complications. Rarely, the technique has been associated with port-site recurrences or intraperitoneal dissemination of disease by laparoscopic gas and/or uterine manipulation.

Whether a minimally invasive procedure is comparable to an open approach must be judged by the ability to accurately dissect appropriate nodal basins, to remove an adequate/representative number of LN, to identify metastatic disease, and by the rates of recurrence. The technique used to remove the uterus/ovaries is not the source of controversy, although TLH and robotic hysterectomy may facilitate removal of larger uteri or assist with cases with poor descensus compared to LAVH. Comprehensive surgical staging allows for appropriate risk stratification to make appropriate treatment recommendations. Multiple reports demonstrated similar node counts for open, laparoscopic, and robotic techniques in the surgical staging of EC (186, 198). In the GOG Lap II trial, median numbers of nodes from pelvic and paraaortic basins, and frequencies of positive nodes were comparable in the surgical arms (186). Despite the potential benefits of laparoscopic surgery, if laparoscopic nodal dissection cannot be performed, conversion to laparotomy is advised when incomplete staging results would yield inadequate information for treatment planning.

Minimally invasive surgery must be performed with an acceptable complication rate to be considered a viable option.

Table 22.11 Selected Robotic Surgery Series in Endometrial Cancer

Study	N (Robot Cases)	Type of Study	Procedure	OR Time (min) (mean/median)	# Nodes (mean/median)
Boggess et al. (2008)	103	Compare to LSC + Open	Hyst + PPALND	191	33
DeNardis et al. (2008)	87	Compare to LSC	Hyst + PPALND	177	19
Veljovich et al. (2008)	25	Compare to LSC + Open	Hyst ± LND	283	18
Holloway et al. (2009)	100	Case series	Hyst + PPALND	171	19
Seamon (2009)	105	Compare to LSC	Hyst + PPALND	242	31
Lowe et al. (2009)	405	Case series	Hyst ± LND	172	14
Lim (2010)	122	Compare to LSC	Hyst + PPALND	147	25

LSC, laparoscopic; Open, laparotomy; Hyst, hysterectomy; PPALND, pelvic paraaortic lymph node dissection; LND, lymph node dissection unspecified.

In one series reporting on complication rates with an institution's first 100 pelvic and paraaortic nodal dissections, conversion to manage complications was required in five to control bleeding, and one to repair a ureteral injury (209). In another group's experience with 150 patients, seven major vascular injuries were reported, but only four patients required laparotomy (210). Querleu et al. reported on intraoperative and postoperative complications of laparoscopic node dissection from 1,192 pelvic and paraaortic nodal dissections (211). Only 13 open procedures were required to complete the nodal dissections, and a laparotomy was required in seven cases to manage complications. Eleven intraoperative vascular injuries were noted, but none required laparotomy to manage. In the GOG Lap 2 study, intraoperative complications were comparable (7.6% open, 9.5% randomized to laparoscopy, 4.9% successful completion of laparoscopy) (186). Postoperative complications and short-term quality of life improvements favored laparoscopy. A meta-analysis of robotic studies for gynecologic conditions noted that for endometrial series, robotic surgery was associated with less blood loss and less frequent conversions to open procedure compared to laparoscopy.

Restaging

One of the more useful roles of minimally invasive surgery is in restaging patients who underwent hysterectomy only. Patients who undergo hysterectomy without nodal dissection and who have pathologic risk factors for potential nodal spread face a difficult dilemma. Patients may elect to receive radiation or chemotherapy (presume nodes are positive), elect observation (presume nodes are negative), or undergo a second operation. A second laparotomy can be difficult to accept. Laparoscopic staging offers the patient a less invasive option to collect information. Childers et al. reported the initial experience with restaging in 13 patients, finding disease in three patients (213).

Recommendations for Minimally Invasive Surgery

Standard of care today includes minimally invasive surgery in the management of EC. Additional training and experience are required for successful completion of these procedures, just as they are with open procedures. The demonstration of comparable surgical endpoints (similar numbers of nodes removed, similar frequency of positive nodes, recurrence rates, and survival) along with shortened hospital stay, quicker recovery, and better quality of life indicators compared to open procedures suggest that appropriate patients should be counseled regarding this option. Challenges remain on how to increase the minimally invasive training of gynecologic oncologists in practice and fellows in training programs. As with open procedures, defining which populations should be considered for nodal assessment and for postoperative therapies continues to be an important research focus.

Surgical Management of Intraperitoneal Disease

The management of patients with Stage IV disease depends on the ability to resect disease. In patients with distant metastasis, there may be a limited role for surgery such as to provide control of vaginal bleeding. In patients with intraperitoneal disease, options include resecting easily removable disease (uterus, adnexa, omentum) versus a more extensive cytoreductive effort. The value of extensive cytoreductive surgery in EC has not been as well studied as it has been in ovarian cancer. Historically, limitations in postoperative therapies (lack of enthusiasm for whole abdominal radiation, marginally effective chemotherapy

regimens, reliance on hormonal therapy) perhaps reduced interest. Several retrospective reports suggest that survival correlates with volume of residual disease (214). Shih et al. reported on 58 patients with Stage IV endometrioid disease treated from 1977 to 2003 of whom 9 had no gross residual, 11 had less than 1 cm residual, and 32 had residual greater than 1 cm (215). The median survival for the entire population group was 19 months; however, median survival was 42 months for patients with no gross residual disease. In a multivariate analysis of the data, residual disease and the use of postoperative adjuvant chemotherapy were independently associated with survival. Bristow et al. demonstrated that optimal cytoreduction (<1 cm) could be obtained in 55% of Stage IV patients, and required omentectomy (93%), peritoneal stripping (65%), and bowel resection (29%) to do it (214). In patients with serous histology, similar survival improvements were seen with optimal debulking of intraperitoneal disease (216).

Surgical Recommendations

The contemporary management of EC has significantly changed. We believe that patients must be appropriately counseled with regards to the presumed benefits of lymphadenectomy as well as the potential risks. Data for the ASTEC and Italian lymphadenectomy trials provide doubt as to the benefit of resecting negative nodes, but both studies clearly demonstrate that nodal disease cannot be found unless one searches for it. The clinician is challenged with finding the "needle in the haystack" in a disease where the baseline rate of nodal metastasis is ~9%. How many patients should undergo a procedure that is not likely to benefit them is balanced by how many patients with unrecognized nodal disease we are uncomfortable with. The marginal benefit achieved by lymphadenectomy and the downstream costs associated with or without its use in terms of adjuvant therapy, outcomes, and quality of life need to be better defined so that patients and physicians can make choices based on good information. Clinical pathologic models that define low-risk populations for whom lymphadenectomy may be safely avoided appear to be promising, but need to be validated prospectively in large series. In the future, biomarker-based testing or sentinel nodal assessment may serve as an alternative to lymphadenectomy, but data is immature at this point to recommend routinely. Increasing the proportion of patients who undergo minimally invasive surgery to manage EC is an important goal and driven by the data. Patients who *a priori* are deemed not to be candidates for staging should be considered for vaginal or minimally invasive hysterectomies. Surgical therapy for EC removes the disease and defines populations at risk for recurrence and death. Surgical staging, or the lack of it, defines patient groups into surgically staged node positive or negative, or unstaged. Comprehensive staging most accurately assigns stage and associated prognosis, although the magnitude of the risk assignment is tempered by the frequency of positive nodes, uterine risk factors, and use of adjuvant therapy. Staging also allows for a more tailored approach to the use of adjuvant therapies. For patients with resectable intraperitoneal disease, cytoreductive surgery can result in optimal volumes of residual disease, and perhaps improved outcomes.

PATHOLOGY

Hyperplasia

The current classification of endometrial hyperplasia accepted by both the International Society of Gynecologic Pathologists (ISGP) and the World Health Organization (WHO) is based

Table 22.12 Classification of Endometrial Hyperplasia

Types of Hyperplasia	Progressing to Cancer (%)
Simple (cystic without atypia)	1
Complex (adenomatous without atypia)	3
Atypical	
Simple (cystic with atypia)	8
Complex (adenomatous with atypia)	29

on the schema of Kurman and Norris (217), which divides hyperplasia on the basis of architectural features into simple or complex and on the basis of cytologic features into typical or atypical (Table 22.12). The resulting classification has four categories as follows: *simple hyperplasia* (SH); *complex hyperplasia* (CH), *simple atypical hyperplasia* (SAH); and *complex atypical hyperplasia* (CAH). SH is defined as an increase in the number of endometrial glands, which may be dilated with little crowding or have an irregular outline and exhibit crowding. CH is characterized by glands with irregular outlines, marked structural complexity, and back-to-back crowding. The designation atypical hyperplasia is used to denote a proliferation of glands exhibiting cytologic atypia, recognized as nuclear enlargement, the presence of nucleoli, or a change from an elongated to a more ovoid or round nucleus. The chromatin may be either evenly or irregularly dispersed. The justification for this classification system rests on three retrospective studies that demonstrate a higher rate of progression of CAH to adenocarcinoma (217–219). It is sometimes difficult to apply this system, which requires one to make a distinction between cytologically atypical nuclei and those without atypical nuclei since a spectrum of nuclear variability actually exists. As noted by Kendall et al., the definitions of architectural complexity and nuclear atypia potentially rest on a multitude of criteria, and some but not all criteria may be fully developed in any given case.

Several reports have addressed the reproducibility of diagnoses of hyperplasia (220). Intraobserver reproducibility was generally found to be moderate to good, whereas interobserver reproducibility was poor to moderate for various diagnostic categories. These studies probably overestimate the interobserver reproducibility since they used expert gynecologic pathologists and specified the classification to be used. In a prospective study by the GOG, neither community-based nor expert panel diagnosis of atypical hyperplasia was highly accurate (66). The current classification of hyperplasia relies on a combination of multiple architectural and cytologic criteria. It is hardly surprising that interobserver reproducibility is relatively low when multiple criteria are used to classify a lesion since each pathologist must assign a relative value or weight to each potentially conflicting criterion. Other factors contributing to low reproducibility include: (a) the fragmentary nature of curettings; (b) the presence of borderline lesions; (c) uncertainty about the significance of focal hyperplasia; (d) the inadequacy of published descriptions and understanding of terms used to define architectural or cytologic atypia; and (e) the difficulty associated with the translation of verbal descriptions into light microscopic interobserver reproducibility for images.

The gross manifestations of endometrial hyperplasia are highly varied. The endometrium is often of diffusely increased thickness (5–10 mm or greater), vaguely nodular, tan, and soft without hemorrhage or necrosis. However, hyperplasia may be focal or multifocal in a background of polyps or cycling endometrium, or even occasionally may be associated with a diffusely

thin endometrial lining. Part of the variability may reflect a reduction in the ET due to prior endometrial sampling. Coexistent adenocarcinoma is present in 1% to 40% of hysterectomies performed to treat hyperplasia, with the latter number reflecting the frequent co-occurrence of carcinoma with atypical CH.

Endometrial Intraepithelial Neoplasia

Based on a combination of morphologic, molecular, and morphometric information, Mutter et al. have proposed an alternative classification scheme to replace the current WHO hyperplasia terminology (221, 222). They have presented data that endometrial intraepithelial neoplasia (EIN) is the histopathologic presentation of a monoclonal endometrial preinvasive glandular proliferation that is the immediate pathologic precursor of endometrioid endometrial adenocarcinoma. Monoclonality and forward carryover of EIN mutations into subsequent carcinoma were the original molecular standards used for EIN diagnosis. Computer-assisted morphometric analysis of more than 20 features was carried out initially, and the three features seen in molecularly defined precancers enabled an objective delineation of histologic diagnostic criteria (the D-score). The principal components assessed included a reduction in the volume of stroma and an increased variability in nuclear shape gland contour. Several of these features have been translated to characteristics that can be assessed subjectively by the surgical pathologist (Fig. 22.3). These features include the following: (a) the area of the glands exceeds that of stroma; (b) nuclear and cytoplasmic features of the affected glandular cells differ from those of the background glands, and may include loss of nuclear polarity or increased nuclear pleomorphism; in the absence of any background glands, a highly abnormal cytology is sufficient; (c) the maximum diameter exceeds 1 mm; (d) benign conditions including disordered proliferation, polyps, and repair are excluded; and (e) the cribriform or maze-like pattern of carcinoma is excluded. There is a high degree of concordance between EIN diagnoses rendered by computer and those made subjectively by pathologists, and either has superior cancer predictive value when compared to the 14-fold increased cancer risk conferred by the presence of atypia compared to lack thereof in the WHO hyperplasia schema. Clinical outcome studies have shown that almost 40% of women with an EIN diagnosis will be diagnosed with endometrial

FIGURE 22.3. A lesion that could be classified in two different systems as either endometrial intraepithelial carcinoma or complex atypical hyperplasia based on gland crowding and cytologic atypia. Note the presence of a residual inactive endometrial gland that may be used as a reference for estimating cytologic atypia.

carcinoma within 1 year and, for those who do not develop cancer within 12 months, a 45-fold increased risk of future EC exists. Correspondingly, absence of an EIN lesion in an initial representative biopsy, including those with only benign hyperplasia, confers very high (99%) negative predictive value for concomitant or future adenocarcinoma.

While EIN shares many features with atypical CH, the two entities are not entirely overlapping. The concept of EIN is appealing since there appears to be a strong biologic basis, with EIN representing a clonal process, while disordered proliferation and hyperplasia remain as diffuse endometrial physiologic responses to an abnormal stimulus (unopposed estrogen stimulation).

Simple Hyperplasia

In SH, the endometrium is thicker than usual, with dilated glands that have outpouchings and invaginations, producing an irregular outline to the enlarged glands. The glands are crowded, the stroma is more densely cellular than usual, and some foam cells may exist within the stroma. Follow-up of patients with this condition reveals little or no progression to carcinoma.

Complex Hyperplasia

The endometrium is increased in thickness by back-to-back glands in cases of CH. Most glands have irregular outlines. The two main features differentiating this from SH are the high ratio of glands to stroma, with some back-to-back glands that have very little intervening stroma. Epithelial stratification is a frequent finding, producing an appearance of two to four cell layers. Mitotic activity is highly variable, but may range to up to ten mitotic figures per ten high-power fields.

Atypical Hyperplasia

Atypical hyperplasia is characterized by cytologic atypia of the glands, which may vary unpredictably according to vagaries of histologic preparation. The architecture may reflect simple or CH, although it is usually complex. The cells lining the glands display nuclear hyperchromatism and nuclear enlargement, and have an increased nucleus-cytoplasm ratio. Nuclei are irregular in size and shape, and have a thickened nuclear membrane, inconspicuous to prominent nucleoli, and a coarse chromatin texture. At times, the nuclei may appear clear with scattered, coarse chromatin clumps.

Progression from Hyperplasia to Cancer

The natural history of endometrial hyperplasia is difficult to define for a variety of reasons, four of which follow: (a) pathologic criteria—criteria and terminology for the various forms of hyperplasia have changed repeatedly; (b) initial sampling—the method of initial diagnosis is often curettage, which removes part or all of the lesion to be studied; (c) coexisting lesions—other lesions such as adenocarcinoma may coexist at the time of diagnosis without our knowledge, since the curettage or biopsy samples only a minority of the endometrium; and (d) subsequent intervention—hormonal or surgical intervention usually interrupts observations of the natural history of the hyperplasia. Nevertheless, there are reasonably good data to support the following assertions: (a) endometrial hyperplasia is commonly a consequence of unopposed prolonged estrogen stimulation; (b) some hyperplasias may regress if the estrogenic stimulus is removed or in response to progestational or antiestrogenic treatment; (c) some hyperplasias coexist with, or progress to, invasive adenocarcinoma; and (d) the probability of progression to adenocarcinoma is related to the degree of architectural

or cytologic atypia. Progression from hyperplasia to carcinoma occurs in only 1% of patients with SH and in 3% of patients with CH (65). Progression from atypical hyperplasia is much higher; 8% of patients with SAH and 29% of those with CAH develop carcinoma (Table 22.12) (65, 217). Glandular complexity superimposed on atypia probably places the patient at greater risk than does cytologic atypia alone, but the point is unsettled.

Pathologic Diagnosis

The ISGP and the WHO last revised the classification of uterine tumors in 2003 (223), and the portion pertaining to carcinomas of the endometrium is presented in Table 22.13. This relatively simple classification scheme accommodates the vast majority of endometrial carcinomas and distinguishes among neoplasms of significantly different prognosis. Mixed carcinomas with two distinctive cell types are relatively common, and are defined as those carcinomas in which the secondary component constitutes at least 10% of the neoplasm.

In most endometrial samples, the distinction of adenocarcinoma from hyperplasia is straightforward. However, a small fraction of problematic cases with complex proliferations truly tax the abilities of experts as well as novices to classify them correctly. The diagnosis of a well-differentiated adenocarcinoma is made in the presence of any of the following criteria: (a) irregular infiltration of glands in an altered fibroblastic stroma; (b) a confluent glandular pattern that results in either a cribriform arrangement or confluent interconnected glands; or (c) extensive papillary growth of epithelium and stroma into glandular lumina (217).

Histologic Grade

The differentiation of a carcinoma is expressed as its grade. Grade 1 lesions are well differentiated and are generally associated with a good prognosis. Grade 2 tumors (Fig. 22.4) are moderately well differentiated and have an intermediate prognosis, and grade 3 reflects poorly differentiated lesions, which frequently have a poor prognosis. Both architectural criteria and nuclear grade are used in the FIGO and ISGP-WHO committee (274) classification of tumors and are applied to endometrioid cell types including

FIGURE 22.4. Endometrioid adenocarcinoma, grade 2. The glandular component is a caricature of proliferative phase glands, with stratification and a shared luminal border to the neoplastic cells. In grade 2 carcinomas, regions of solid neoplastic growth occupy between 5 and 50% of the surface area of the carcinoma.

variants and mucinous carcinomas (Table 22.13). In contrast, serous, clear-cell, and undifferentiated carcinomas are considered high grade by definition, and are not graded numerically. The architectural grade is determined as follows: grade 1—an adenocarcinoma in which less than 5% of the tumor growth is in solid sheets; grade 2—an adenocarcinoma in which 6% to 50% of the neoplasm is arranged in solid sheets of neoplastic cells; grade 3—an adenocarcinoma in which greater than 50% of the neoplastic cells are in solid masses. Regions of squamous differentiation are excluded from this assessment. The FIGO rules for grading state that notable nuclear atypia, inappropriate for architectural grade, raises the grade of a grade 1 or grade 2 tumor by one. However, FIGO did not define notable nuclear atypia. Justification and clarification for this modification based on extreme nuclear pleomorphism were provided in a recent GOG study. For 715 women with nonserous endometrial carcinomas, three nuclear grades were defined as follows: grade 1—round to oval nuclei with even distribution of chromatin and inconspicuous nucleoli; grade 2—irregular, oval nuclei with chromatin clumping and moderate-size nucleoli; and grade 3—large, pleomorphic nuclei with coarse chromatin and large, irregular nucleoli. Patients with tumors of architectural grade 1 or 2, but with a majority of cells having nuclei of grade 3, had a significantly worse behavior, justifying an up-grading by one grade (225).

Taylor et al. (226) proposed a two-tiered system for grading endometrial carcinoma based on a study of 85 patients with Stage I and II EC. They divided tumors at 10% intervals based on the percentage of solid tumor growth and found that tumor recurrences were confined to the subset with greater than 20% solid tumor. They also found that this binary division yielded a higher degree of interobserver agreement than three architectural grades. Lax et al. (227) have presented preliminary data on a binary architectural grading system based on the presence of greater than 50% solid growth, a diffusely infiltrative growth pattern, and tumor cell necrosis. These methods will need to be replicated in a larger patient population before an assessment of their prognostic utility can be made.

Cell Types

Endometrioid Adenocarcinoma. Endometrioid adenocarcinoma is the most common form of carcinoma of the endometrium, comprising 75% to 80% of the cases (55). It varies from well

differentiated to undifferentiated. Characteristically, the glands of endometrioid adenocarcinoma are formed of tall columnar cells that share a common apical border, resulting in a smoothly delineated, round or oval luminal contour. With decreasing differentiation, there is a preponderance of solid growth rather than gland formation, and the cells lining glandular lumina become more numerous but not necessarily clearly stratified. Stromal invasion manifested by a desmoplastic host response or vascular invasion is often not evident in the biopsy or curettage specimen.

Villoglandular Carcinoma. There has been considerable confusion about the definition and significance of papillary carcinoma of the endometrium. A variety of cell types of endometrial adenocarcinoma with differing biologic behavior, including serous, clear-cell, mucinous, and villoglandular carcinoma, may grow in a papillary fashion. Thus, the adjective *papillary* does not represent a cell type but rather an architectural pattern.

Villoglandular carcinoma is a relatively common subtype of endometrioid adenocarcinoma characterized by neoplastic columnar cells covering delicate fibrovascular cores. The apical cytoplasmic borders are straight, the nuclei are usually low grade, and the tumor cells architecturally resemble those of other endometrioid adenocarcinomas, with which they are often admixed. In the largest study to date, villoglandular carcinomas were better differentiated than endometrioid carcinomas, but the age at diagnosis, depth of myometrial invasion, nodal spread, and survival were similar to those of endometrioid carcinomas, justifying their classification as a subtype of endometrioid adenocarcinoma (228).

Secretory Carcinoma. Secretory carcinoma is a variant of endometrial carcinoma, but it is unusual and represents no more than 2% of the cases (229). It is identified by its well-differentiated glandular pattern, consisting of columnar epithelial cells containing intracytoplasmic vacuoles similar to secretory endometrium. It is usually grade 1 architecturally and by nuclear features. There is minimal cellular atypia, stratification, and pleomorphism. The intracellular secretions are not mucin but glycogen. The cellular features of secretory carcinoma differentiate it from clear-cell carcinoma, which is more papillary with more pleomorphic nuclei. By its lack of mucin, secretory carcinoma may be differentiated from mucinous carcinoma. Recognition of secretory carcinoma is important because it has a less virulent clinical course (230), although the clinical profile of patients is similar to that of patients with adenocarcinoma.

Ciliated Carcinoma. Ciliated carcinoma is rare. Ciliated cells are more commonly identified in endometrial hyperplasia and in benign metaplasia (tubal metaplasia), but they may occur in endometrioid carcinomas. Associated with prior exogenous estrogen use, this cell type is reported to have a good prognosis (231).

Adenocarcinoma with Squamous Differentiation. Foci of squamous differentiation are found in about 10%–25% of endometrial adenocarcinomas (Fig. 22.5). Historically, the tumors were sometimes separated into adenoacanthoma or adenosquamous carcinoma based on whether the squamous component appeared histologically benign or malignant (232, 233). However, in about 30% of cases, the squamous component is not clearly benign or malignant. In a GOG study of early-stage disease, it was noted that these tumors with squamous regions behave in a fashion similar to endometrioid carcinomas without squamous differentiation (234). The squamous areas usually mirror the degree of differentiation, which, coupled with assessment of histologic grade and other conventional prognostic factors, is thus more useful for prognostication and determination of adjuvant therapy than the historic terms *adenoacanthoma* and *adenosquamous carcinoma*, which are confusing and should be abandoned.

FIGURE 22.5. Endometrioid adenocarcinoma with squamous differentiation. The squamous component may form keratin pearls, but more often simply is characterized by acquisition of more abundant, deeply eosinophilic cytoplasm and distinct cell borders (upper right of figure). The squamous component may appear histologically benign or malignant.

Mucinous Adenocarcinoma. Mucinous adenocarcinoma is rare in the endometrium in contrast to its high frequency in the endocervix. It has been reported to represent between 1% and 9% of endometrial adenocarcinomas (235), but the former figure is probably more accurate. If present as the major cellular component of an endometrial carcinoma, this tumor resembles mucinous carcinoma seen in the ovary and endocervix. Two patterns occur: In one, the cells are columnar with basally oriented nuclei; in the other, the cells are more pseudostratified, as in an adenocarcinoma of the colon or mucinous carcinoma of the ovary (Fig. 22.6). The characteristic cellular pattern should represent over 50% of the entire tumor. Typically, there are either papillary processes or cystically dilated glands lined by columnar or pseudostratified columnar epithelium. The cytoplasm is positive for carcinoembryonic antigen (CEA), mucicarmine, and periodic acid-Schiff stain (PAS), but it is diastase resistant. This tumor differs from clear-cell carcinoma and secretory endometrium by having more mucin and less glycogen. The glandular architecture is usually well maintained, and most are well

FIGURE 22.6. Mucinous adenocarcinoma. The apical cytoplasm cells as well as the lumens of glands are filled with a pale basophilic mucoid product.

FIGURE 22.7. Serous carcinoma often arises in an otherwise endometrium of older women, and superficially, portions usually have a highly papillary architecture.

differentiated (235). To establish the origin in the endometrium, exclusion of a primary endocervical tumor may be required. If the endocervical sample demonstrates the same neoplasm, the site of origin must be carefully established because this cell type is common in the endocervix (236). Neither the pattern, the type of mucin staining, nor the presence of CEA can reliably distinguish mucinous adenocarcinoma of the endometrium from its more common counterpart in the endocervix (237). Mucinous carcinoma of the endometrium has the same prognosis as common endometrial carcinoma.

Serous Carcinoma. Serous carcinoma of the endometrium closely resembles serous carcinoma of the ovary and fallopian tube because its papillary growth and cellular features are similar (Figs. 22.7 and 22.8). It is usually found in an advanced stage in older women. Fibrous papillary fronds are lined by epithelial cells, which are almost devoid of cytoplasm, but which manifest stratification, atypism, pleomorphism, mitotic figures, and bizarre forms. These fronds often detach or demonstrate a terminal growth of tiny papillary excrescences and individual cells, which detach easily (Fig. 22.7). A second pattern of irregular

FIGURE 22.8. Serous carcinoma is characterized by high-grade cytologic atypia in cells that do not share a common apical border. The papillary architecture may be replaced by gaping glands at the interface with the myometrium.

gaping glands lined by cuboidal cells with scalloped, apical borders may be present, particularly in the deeper aspect of the tumor (Fig. 22.8). Lymphatic invasion is commonplace in the myometrium. Distinction from clear-cell carcinoma may be difficult but can usually be accomplished on the basis of a greater degree of papillary processes, greater nuclear atypia, and less cytoplasm in papillary serous carcinoma. Psammoma bodies are frequently observed in serous carcinoma, but solid growth is more common in clear-cell carcinoma.

Serous carcinoma represents approximately 10% of endometrial carcinomas, which is fortunate because it is an aggressive tumor. The tumors often deeply invade the myometrium, and unlike typical endometrioid adenocarcinoma, there is a propensity for peritoneal spread. Unfortunately, advanced-stage disease or recurrence is common even when serous carcinomas are apparently only minimally invasive or even confined to the endometrium in polyps (146, 238, 239). Since the metastatic disease is often identified only microscopically, about 60% of patients are up-staged following complete surgical staging (146). A report by Wheeler et al. (240) stressed the prognostic importance of meticulous surgicopathologic staging. They and others found that serous carcinoma truly confined to the uterus had an overall excellent prognosis, whereas patients with extrauterine disease, even if only microscopic in size, almost always suffered recurrence and death from tumor (241, 242).

EIC is a histologically distinctive lesion that is specifically associated with serous carcinoma of the endometrium (243–247). Serous carcinomas most often arise from a background of atrophy or polyps rather than hyperplasia (243, 244, 245), and they are not epidemiologically related to unopposed estrogen stimulation. EIC has been proposed to represent a form of intraepithelial tumor characteristic of serous carcinoma, and it is the precursor to invasive serous carcinoma. Mutations in p53 that can be detected immunohistochemically as overexpression of the antigen are found in most cases, and the mutation is shared with that found in the invasive serous carcinoma (Fig. 22.9). EIC is usually found in the endometrium harboring a serous carcinoma (244), but occasionally occurs in the absence of any invasive carcinoma. In such cases, it may be associated with synchronous serous carcinoma in the peritoneum (245).

Clear-Cell Carcinoma. Clear-cell adenocarcinoma of the endometrium is generally recognized and defined on the basis of the

distinctive clearing of the cytoplasm of neoplastic cells growing in any combination of solid, glandular, tubulocystic, or papillary configurations. About 4% of endometrial adenocarcinomas are of clear-cell type (248–250). In contrast with the diethylstilbestrol (DES)-related clear-cell carcinomas of the vagina and cervix, clear-cell carcinoma of the endometrium is almost exclusively a disease of menopausal women. The mean age at diagnosis is about 68 years, which is similar to that of serous adenocarcinoma and about 6 years older than that of typical endometrial adenocarcinoma (250). It is a biologically aggressive neoplasm, with a 5-year survival rate varying from only about 20% to 65% (5, 248, 250).

The hallmark of clear-cell carcinoma is the presence of neoplastic cells with optically clear cytoplasm, reflecting an abundance of glycogen. Four basic architectural patterns of clear-cell adenocarcinoma exist, including solid, glandular, tubulocystic, and papillary, but most cases display an admixture of patterns. The solid pattern consists of masses of large neoplastic cells of polygonal shape with clear to faintly eosinophilic cytoplasm and distinct cell membranes. The glandular pattern is reminiscent of the tubular glands of endometrioid adenocarcinoma, whereas the tubulocystic pattern is formed of dilated spherical-appearing glands. The papillary pattern is architecturally identical to that of serous carcinoma, with generally short, branching fibrovascular cores, often hyalinized, covered by neoplastic cells. The latter three patterns often have lining cells with a hobnail appearance, resulting from the scalloped apex of individual neoplastic cells that project along the surface (Fig. 22.10).

Squamous Carcinoma. Although focal squamous differentiation is common in endometrial adenocarcinoma, pure squamous carcinoma of the endometrium is extremely rare, representing less than 1% of endometrial carcinoma, and with only about 60 reported cases (251, 252). Most patients are postmenopausal, and the average age at diagnosis is about 65 years. Squamous carcinoma of the endometrium is established as primary in the endometrium after a cervical origin is ruled out. There must be no connection with or spread from benign or malignant cervical squamous epithelium. It is often associated with cervical stenosis, pyometra, and chronic inflammation. About 60% of the cases have been confined to the uterus, and the prognosis for these patients has been relatively good. In contrast, less than 15% of women with advanced-stage disease have survived

FIGURE 22.9. Endometrial intraepithelial carcinoma is the precursor lesion of invasive serous carcinoma. It shares histologic and immunohistochemical features with serous carcinoma, including frequent overexpression of p53. In this case, there is nuclear localization of stain in EIC (on right), but no staining of the benign glands or stroma of the polyp in which it has arisen (on left).

FIGURE 22.10. Clear-cell carcinoma. In this tumor, a tubulocystic pattern with a lining of hobnail cells is present on the left, while a solid pattern is present on the right. Any mixture of solid, tubulocystic, papillary, or glandular architecture may occur.

2 years after diagnosis. Histologic grade does not appear to correlate with the probability of survival.

Undifferentiated Carcinoma. Undifferentiated carcinoma of the endometrium has been described as a distinct tumor type. These neoplasms are composed of a monotonous proliferation of medium sized, round or polygonal cells growing in sheets with no specific pattern. Mitotic figures are numerous. No glandular, squamous, or sarcomatous differentiation is detected in routinely stained sections. Keratins and epithelial membrane antigen are detected by immunohistochemistry in fewer than 20% of the cells in most cases, in contrast to diffuse staining in most high-grade endometrioid carcinomas. Selected cases may contain neurosecretory granules in a minority of the cells as demonstrated by immunohistochemical stains. Neurosecretory products are apparently not released into the patient's circulation or are not in an active form because no affected women have manifested symptoms. Most patients present with tumors of advanced stage, and the behavior is usually aggressive. A *glassy cell carcinoma* has also been described, which comprises less than 1% of endometrial carcinomas. It is characterized by cytoplasm that has a ground-glass appearance, as in the cervix. Although few cases have been reported, like serous and clear-cell carcinomas, glassy cell carcinoma appears to be aggressive (253).

Mixed Cell Type. If an endometrial carcinoma manifests two or more different cell types, each representing at least 10% or more of the tumor, the term *mixed cell type* is appropriate.

Metastatic Carcinoma to the Endometrium. Malignancies in other organs may metastasize to the endometrium. The most common extragenital sites are breast, stomach, colon, pancreas, and kidney, although any disseminated tumor could involve the endometrium. The ovaries are the most likely genital sources of metastasis. Metastatic carcinoma presents as abnormal vaginal bleeding, and the initial specimen for evaluation is usually a biopsy or curetting. Although the metastatic disease may appear as a large focus, individual and small groups of malignant cells may subtly intermingle with normal endometrium or myometrium. Lymphatics are usually involved. Special stains for mucin, CEA, or melanin may suggest that the cells are not of endometrial origin. In some instances, unusual cell types, such as signet-ring cells, may be present, suggesting a metastasis from the gastrointestinal (GI) tract. It is uncommon but not exceptional for the endometrial sample to be the first indication of an occult primary lesion (254).

Simultaneous Tumors. Cancers of an identical cell type may be discovered in the ovary and endometrium simultaneously (255). Usually, the primary site is assigned to the area having the largest tumor mass and most advanced stage. In certain situations, primary malignancies in the endometrium and ovary may coexist. This "field effect" of the "extended müllerian system" may occur in 15% to 20% of endometrioid carcinomas of the ovary (256). In a review of a GOG study of 74 patients with simultaneously detected endometrial and ovarian carcinoma with disease grossly limited to the pelvis, only 16% of women suffered a recurrence of disease, with a median follow-up of 80 months. This group of patients was atypical, with 86% having endometrioid histology in both sites. Recurrence was statistically related to the presence of microscopic metastases or high histologic grade (257).

Carcinomas of more advanced histologic grade and cell type are more difficult to assign to the field effect because of a higher probability of invasion and metastasis at the time of surgery (230). If the endometrial tumor is less than 5 cm in diameter, the ovarian lesion is unilateral, invasion is less than the middle third, vessels are not involved, and the endometrial carcinoma is well differentiated; metastasis to the ovary is unlikely (258).

PATHOLOGIC FACTORS OF PROGNOSTIC SIGNIFICANCE

Pathologic information has been used to estimate risk of nodal metastasis and to define prognosis (recurrence, survival) in EC. Prognostic factors have been identified within each stage of EC, and the discussion of prognostic factors is probably best served by discussing factors within comparably staged groups, more so than as isolated factors. For example, in GOG 99, which compared observation to pelvic radiation therapy in patients with Stage I–II EC and pathologically negative LN, a model based on combinations of patient age and tumor grade, depth of invasion, and lymphovascular space invasion (LVSI) could predict patients at highest risk for recurrence (121). Similarly, PORTEC identified a combination of 2 of 3 factors; age greater than 60, grade 3 tumor, and depth of invasion greater than 50% which defined patients at high risk for local-regional failure when managed by surgery alone (135). Increasingly, risk models are used to counsel patients as to the marginal benefit of postoperative therapies.

Predicting Nodal Disease

Based on pathologic information available at the time of surgery, the risk for nodal metastasis may be estimated. Physicians who selectively perform nodal dissections frequently do so based on the presence of uterine risk factors that suggest the potential for nodal disease. In patients who did not undergo a nodal dissection at the time of hysterectomy, decisions to offer radiation therapy are commonly based on the estimation of risk for nodal disease based on uterine risk factors. In the surgical pathologic study GOG 33, pelvic and paraaortic nodal disease was more frequent with increasing grade (percentage of pelvic nodal metastases: 3% grade I, 9% grade II, 18% grade 3), depth of invasion (1% endometrium only, 5% inner one-third, 6% middle one-third, 25% outer one-third myometrial invasion), and LVSI (27% with LVSI, 7% without LVSI) (55). Pelvic and paraaortic nodal metastases were also more common with cervical involvement, when peritoneal cytology was positive, and when extra-nodal (adnexal, intraperitoneal sites) disease was found. In a multivariate model, grade, depth of invasion, and intraperitoneal disease were independent predictors of pelvic nodal disease. In a further analysis of patients participating in GOG 33, 47 of 48 patients with paraaortic nodal disease had one or more factors of palpably enlarged paraaortic nodes, grossly positive pelvic nodes, gross adnexal disease, or outer one-third invasion (57). Despite the use of pathology to help predict nodal disease, many believe that lymph node assessment is superior as it provides actual information on nodal status, as opposed to an estimate, which can then be used to tailor therapy. As previously discussed, patients at very low risk for nodal involvement may also be specified by uterine risk factors (size, grade, depth of invasion) (148–151).

Prognostic Factors

FIGO Stage

Prognostic factors may be used to categorize patients into high- and low-risk groups and to guide the use of adjuvant therapies. Understanding these factors also allows for the development of novel strategies to reduce risk of recurrence or alter patterns of disease failure. Overall, the patients at highest risk for recurrence and death have spread of disease outside of the uterus, which is reflected by FIGO stage (57). The prognostic utility of surgicopathologic stage has been confirmed in multiple studies of large numbers of patients, using both univariate and

multivariate analysis (55, 259–261). FIGO surgical stage is often the single strongest predictor of outcome for women with endometrial adenocarcinoma in studies using multivariate analyses. Although the FIGO clinical staging system of 1971 was generally useful, retrospective comparison of the two methods demonstrated the clear superiority of surgicopathologic staging over clinical staging in predicting outcome.

Patients with intraperitoneal or distant metastases (Stage IV) have the poorest prognosis with 5-year survival ranging from 20% to 25% (5). In GOG 122 comparing whole abdominal radiation therapy to doxorubicin/cisplatin chemotherapy as primary therapy for EC patients with less than 2 cm residual disease Stage III–IV, Stage IV (compared to Stage III) disease was an independent predictor of shorter PFS (HR, 2.29) and survival (HR, 1.9) (262). Gross intraperitoneal spread frequently indicates the presence of larger tumor burden as many patients with intraperitoneal disease also have adnexal and nodal disease. In GOG 33, 51% of patients with gross intraperitoneal spread had positive pelvic nodes, whereas only 7% without spread had positive pelvic nodes (55). Prognosis may be modified by the volume of residual disease after cytoreductive surgery (214–215).

Patients with nodal metastases (Stage IIIC disease) also have poorer prognosis compared to node-negative populations. FIGO data show 5-year survival to be 57% in Stage IIIC patients compared to 74% to 91% when nodes are negative (Stage I–II) (5). Patients with positive pelvic but negative paraaortic nodes have a better prognosis compared to those with paraaortic disease (57, 263, 264). For example, Hoekstra and colleagues reported a series of 85 patients with Stage IIIC disease who had a 5-year survival of 61% (264). Patients with positive pelvic nodes had a 5-year survival of 70% compared to 49% when paraaortic disease was present. In 2009, FIGO staging was revised for patients with positive pelvic nodes/negative paraaortic nodes who were reclassified as Stage IIIC1, and patients with any positive paraaortic node were classified as Stage IIIC2 (79). This change has been validated in two recent reviews (265, 266). Two retrospective series have also suggested that patients with nodal disease in addition to positive cytology, adnexa, or serosa have poorer PFS or survival compared to those patients with positive nodes alone (140, 263). Lymphadenectomy (139, 163–174), complete surgical resection of bulky nodes (267), and use of chemotherapy (164, 262, 265–268) have been suggested to improve outcomes in patients and modify the prognostic effect of nodal disease.

Patients with FIGO 1988 Stage IIIA disease represent a heterogeneous population having adnexal, peritoneal cytology, and/or serosal involvement, but with negative LN. Positive peritoneal cytology as the sole upstaging factor was dropped in the 2009 FIGO staging revisions as a stage-defining characteristic (79). In the GOG 33 study, 12% of all patients had positive cytology, and of these, 25% had positive pelvic nodes and 19% had metastases to paraaortic LN (55). Six percent of clinical Stage I–II patients have spread of tumor to the adnexa, and of these, 32% have pelvic node metastases compared with 8% pelvic node positivity if adnexal involvement is not present (55). Twenty percent have positive paraaortic node metastases, which is four times greater than if adnexal metastases were not present.

For patients who are completely staged and found to have no extrauterine disease, 4% to 6% of patients have positive cytology as an isolated finding (55). Published opinions are mixed about the significance of this finding (269, 270). In a review of the literature, Wethington categorized patients into groups based on low-risk uterine features (grade 1–2, <50% depth of invasion, no lymphovascular space invasion) with positive peritoneal cytology. In this group, positive cytology occurred in 11% of cases, and had a recurrence rate of 4%. Patients with higher-risk features plus positive cytology had a 32% risk of recurrence (271). Saga reported that positive peritoneal cytology alone in staged patients ($n = 32$) was associated with a 5-year survival of 87%; however, this was worse than the 97% survival seen in

cytology-negative patients (272). In a series of 57 patients with FIGO Stage IIIA (1988) disease, cytology appears to carry the same significance as adnexal involvement and was an independent predictor of prognosis (273).

Histologic Cell Types

The histologic classification of endometrial adenocarcinoma is important not only because it facilitates the recognition of lesions as carcinoma, but also because the cell type has consistently been recognized as being important in predicting the biologic behavior and probability of survival. Endometrioid adenocarcinoma accounts for the majority of tumors in the uterine corpus and carries a relatively favorable prognosis. Consequently, the virulence of other cell types is usually related to endometrioid adenocarcinoma.

Adenocarcinoma with squamous differentiation is similar to typical endometrioid adenocarcinoma with respect to the distribution by age and frequency of nodal metastasis, and is associated with a slightly increased probability of survival. *Villoglandular carcinoma* has a biologic behavior similar to that of endometrioid adenocarcinoma (228, 274). *Serous carcinoma* has been considered an aggressive histologic type, with OS rates varying from 40% to 60% at 5 years (5, 238, 275). *Clear-cell carcinoma* also has a highly aggressive behavior, with 5-year survival rates of 30% to 75% (276, 277). One of the problems with using histology as a marker for prognosis is that serous cancers are more likely to have spread at presentation than endometrioid tumors. Patients with serous or clear-cell tumors present with Stage III–IV disease in 41% and 33%, respectively, compared to 14% with endometrioid type (5). Studies suggest that 40% to 70% of serous tumors will have extrauterine spread at presentation; therefore, complete surgical staging is warranted in this tumor type (146). Given this level of disease spread, it is not surprising that unstaged/clinical Stage I serous patients appear to have similar prognosis to Stage III–IV endometrioid types. Once patients with serous or clear-cell tumors are appropriately allocated into the correct stage, the importance of histology appears to be less (278–281). For example, Creasman et al. evaluated FIGO data and showed that patients with Stage I serous tumors had comparable outcomes to those with Stage I, grade 3 endometrioid tumors. Five-year survival for Stage IB and IC serous tumors was 81% and 55% compared to 84% and 66% for grade 3 tumors (281). In advanced and recurrent EC patients participating in phase 3 GOG chemotherapy trials, response rate to chemotherapy was not associated with histologic type, and serous tumor type was not independently associated with PFS (16).

Grade

The degree of histologic differentiation has been considered to be an indicator of tumor spread. The GOG and other studies have confirmed that as grade becomes less differentiated, there is a greater tendency for deep myometrial invasion and, subsequently, higher rates of pelvic and paraaortic lymph node involvement (55, 282). Survival has also been consistently related to histologic grade, and in a GOG study of more than 600 women with clinical Stage I or occult Stage II endometrioid adenocarcinoma, the 5-year relative survival was as follows: grade 1, 94%; grade 2, 84%; grade 3, 72% (57). In patients with early-stage EC participating in the PORTEC trial, the risk of cancer-related death for patients with grade 3 tumors was 4.9 compared to grade 1–2 tumors (127).

Myometrial Invasion

Deep myometrial invasion is one of the more important factors correlated with a higher probability of extrauterine tumor spread, treatment failure, and recurrence, and with diminished

FIGURE 22.11. Myometrial invasion by endometrial adenocarcinoma may be accompanied by a desmoplastic reaction, but often no such reaction is present, as in this case.

probability of survival (Fig. 22.11) (121, 283). In a GOG study of over 400 women with clinical Stage I and occult Stage II endometrioid adenocarcinoma, the 5-year relative survival was 94% when tumor was confined to the endometrium, 91% when tumor involved the inner third of the myometrium, 84% when the tumor extended into the middle third, and 59% when the tumor invaded into the outer third of the myometrium (57). Even in node-negative patients, deep myometrial invasion retains prognostic information. For example, Mariani et al. reported that for Stage I (node-negative) patients, deep invasion (>66% myometrial invasion) was an independent predictor for recurrence and distant site of failure (284).

Lymphovascular Space Invasion

Several studies have suggested that lymphatic space invasion (LVSI) is a strong predictor of recurrence and death, and is independent of depth of myometrial invasion or histologic differentiation (Fig. 22.12) (285). In a retrospective series of 628 surgically staged patients, the presence of high intermediate

FIGURE 22.12. Lymphatic invasion by endometrial adenocarcinoma. Nests of neoplastic cells occupy the lumen of an endothelial lined space. Since artifactual retraction of stroma around tumor may simulate lymphatic spaces, true lymphatic invasion is best assessed in the myometrium adjacent to the tumor.

risk uterine (H-IR) characteristics and LVSI were associated with nodal metastases (285–287). The odds ratio (OR) for nodal disease was 4.4 with H-IR factors, and 11 for LVSI. In this series, LVSI and H-IR features were independently associated with PFS and survival. Zaino et al. (261) found that LVSI was a statistically significant indicator of death from tumor in early clinical stage but not early surgical stage endometrial adenocarcinoma. This suggests that lymphatic invasion helps to identify patients likely to have spread to LN or distant sites, but that its importance is diminished for those in whom thorough sampling of nodes has failed to identify metastasis. Vascular space invasion or capillary-like space (CLS) involvement with tumor exists in approximately 15% of uteri containing adenocarcinoma (55, 286). Pelvic LN are positive in 27% of cases, which is four times more often if malignant cells are found in the CLS than if absent. The risk of paraaortic node metastases when LVSI was present was 19%, which is a six-fold increase over negative CLS involvement (55). Lymphovascular invasion is identified in 35% to 95% of serous carcinomas of the endometrium, where it has generally been associated with an elevated risk of tumor recurrence or death from disease (275).

Patterns of Failure

Another way to approach pathologic information is to understand the pathologic relationships that predict particular patterns of failure. For example, in patients with pathologic negative-node, Stage I EC, pelvic sidewall recurrences are rare, and failures occur most frequently at the vaginal cuff or at distant sites (121, 288, 289). High-risk Stage I patients who do not undergo nodal dissections have both pelvic sidewall and distant sites of failure, even with routine use of radiation therapy (138). Patients with node-positive disease frequently have recurrences at distant sites, with rare intra-abdominal failures (140, 141, 264). Patients with Stage IV/intraperitoneal disease most commonly fail in the peritoneal cavity. The implications of patterns of failure data are that we may choose our postoperative therapies better by defining patterns of failure for a particular stage distribution or based on the presence of risk factors. The Mayo Clinic group has advocated this approach following a review of patterns of failure data from their group (284, 290–293). For example, these investigators suggested that hematogenous, lymphatic, and peritoneal failures could be predicted based on pathologic factors, and that therapy should be directed to reduce failures at these sites depending on pathologic information (56). Whether their finding can be validated in a prospective manner, or if existing therapies effectively control disease at particular sites needs to be evaluated.

GENERAL MANAGEMENT

Results of Standard Therapy and Their Sequelae

Early uncontrolled trials suggested that progestin therapy after surgery or irradiation was associated with a decreased risk of recurrence in patients with disease confined to the uterus (294). However, large prospective, randomized trials failed to show a survival advantage (295–297). Radiation therapy has been and remains the standard adjuvant treatment modality for most patients at risk for recurrence. This standard continues to evolve, however. An older, poorly designed adjuvant cytotoxic chemotherapy showed no benefit for patients treated with single-agent doxorubicin and arrested interest in adjuvant chemotherapy for many years (298). By 2006, two prospective trials comparing

radiation therapy to chemotherapy demonstrated similar outcomes for patients treated with chemotherapy or radiation therapy (297, 298). Adjuvant chemotherapy improved PFS and survival in patients with advanced-stage disease compared to whole abdominal radiotherapy, suggesting an important role for first-line therapy that includes chemotherapy (262). Current research focuses on whether outcomes may be improved by adding chemotherapy either sequentially or concomitantly with radiation.

ADJUVANT RADIATION THERAPY

Radiation therapy continues to play an important role in the management of EC, although its role is evolving. It is used adjvantly, as definitive treatment for patients who are medically inoperable, for local recurrence, and for palliation. Historically, patients were treated with preoperative intracavitary brachytherapy with or without external beam radiotherapy followed by hysterectomy. This approach has not been completely abandoned but is used infrequently and usually only in patients with gross cervical involvement. Today, most patients undergo primary surgery; then, depending on final pathological review, the need for radiotherapy is determined. Radiation can be delivered with external beam irradiation with or without brachytherapy. Brachytherapy can be delivered by interstitial treatment, where needles are placed into the tissues at risk under general anesthesia and postoperatively loaded with radioactive sources. More commonly, brachytherapy is intracavitary where a device is inserted into an anatomic cavity such as in the uterus or vagina. Brachytherapy doses can be delivered with low-dose-rate ^{137}Cs sources (LDR), high-dose-rate ^{192}Ir sources (HDR), and with ^{192}Ir pulse dose rate (PDR). With LDR, the patient is admitted to the hospital for insertion and delivery, and is usually at bed rest for delivery. This method exposes other personnel to irradiation, is often more costly, and places the patient at risk for deep venous thrombosis and other medical complications. HDR is typically done as an outpatient and avoids radiation exposure to additional personnel, although frequently, more sessions are required. PDR also spares treating personnel radiation exposure, but requires hospital admission.

Early-Stage Disease

Most of the data on adjuvant radiation in EC pertain to patients with early-stage (I–II) disease, as this is the most common presentation. The role of radiation in this group of patients, however, has been undergoing significant scrutiny in the last 10 years. The questions to be resolved are elucidating the benefits of radiation, clarifying which patients will be best served by this additional therapy, and determining the most appropriate radiation strategy.

Benefit of Adjuvant Radiation

Two prospective, randomized trials compared surgery alone to surgery and postoperative external beam radiation. The first trial was conducted by the GOG (study 99) where 392 patients with Stage IB–IIB EC who underwent total abdominal hysterectomy/bilateral salpingo-oophorectomy (TAH/BSO) and pelvic/para-aortic lymph node sampling were randomized to observation ($n = 202$) or postoperative pelvic radiation ($n = 190$) to a total dose of 50.4 Gy in 28 fractions (121). The study was designed to allow for an 80% chance of detecting a 58% decrease in the recurrence hazard rate and a 56% decrease in the death hazard rate. Recurrence free interval (RFI) was the primary endpoint

with all-cause survival as well as recurrence-free survival as secondary endpoints. With a median follow-up of 68 months, the 4-year survival rate was 92% in the radiation arm compared with 86% in the observation arm (Relative hazard [RH], 0.86; $p = 0.557$). The estimated 2-year cumulative incidence of recurrence was 3% versus 12% in favor of the irradiation arm (RH, 0.42; $p = 0.007$), indicating that radiation decreased the hazard rate of recurrence by the required 58%. Specifically, the rate of vaginal recurrence, the most frequent area of recurrence, was 6.4% (13 out of 202) in the surgery alone arm compared to 1.05% (2 out of 190) in the radiation arm. Of interest, these two patients in the surgery arm that recurred were randomized to radiation but refused it. In addition, the estimated risk of death from any cause was 14% less in the RT arm, but was nonsignificant. More than half of the deaths were from causes other than treatment or endometrial carcinoma, and the paper points out that it was therefore not adequate to detect an OS difference, a point often forgotten by many physicians. The subgroup termed HIR accounted for two-thirds of the cancer-related deaths and recurrences, and has become the population for further study in currently open trials. The definition of HIR by GOG is determined by the combination of age and risk factors, including grades 2 or 3, outer 1/3 myometrial invasion and lymphovascular space invasion. Patients are considered to be HIR if they are ≥ 70 with one risk factor, ≥ 50 with two risk factors, or ≥ 18 with all risk factors. The absolute benefit was a 19% decrease in cumulative recurrence in this HIR subgroup. These patients have higher risk factors than the majority low-risk GOG 99 population, including grades 2 or 3 disease, outer third myometrial invasion, more advanced age, and lymphovascular space invasion. In this HIR patient population, the 4-year cumulative recurrence was 27% without irradiation compared to 13% with irradiation. In contrast, for the low-risk population there was a 6% versus 2% recurrence rate in unirradiated compared to the irradiated enrollees. The currently open GOG 0249 randomizes this HIR population between cuff brachytherapy followed by three cycles of carboplatin and paclitaxel versus pelvic irradiation with either 3D conformal therapy or IMRT to 4,500–5,040 cGy in 25–28 fractions with an optional boost with defined high-risk factors to further refine the roles of chemotherapy and radiotherapy.

The second trial was the PORTEC study where 714 patients with Stage IB grade 2,3 and IC grade 1,2 were randomized after TAH/BSO without lymph node sampling to observation ($n = 360$) or pelvic radiation ($n = 354$) to a total dose of 46 Gy in 23 fractions (127). With a median follow-up of 52 months, the 5-year vaginal/pelvic recurrence rate was 4% in the radiation arm compared to 14% in the observation arm ($p < 0.001$). The corresponding 5-year survival rates were 81% and 85%, respectively ($p = 0.37$). In patients with HIR features by the PORTEC definition (where intermediate risk factors were outer-half invasion, grade 3, or greater than 60 years of age, but excluded deeply invasive high-grade tumors, and where patients were deemed HIR with two of the three factors), the recurrence was reduced from 23% to 5% with adjuvant irradiation. It should be noted here that this is different from the GOG HIR definition, and likely a much lower-risk population. An update with a median follow-up of 13.3 years has been recently published (301). The actuarial 15-year locoregional recurrence was statistically different at 6% versus 15% for those with adjuvant irradiation compared to observation with no statistical difference in OS or failure-free survival, distant metastases, or secondary cancers. Most recurrences in the observation arm were vaginal (11% of the 15%).

An additional trial, PORTEC II, was completed as a follow-up study (128). The study population was HIR PORTEC patients. As in PORTEC I the patients underwent a TAHBSO without lymph node dissection and were randomized to 46 Gy in 23 fractions of external beam irradiation or vaginal brachytherapy

alone, with either 21 Gy in three fractions of HDR therapy or 30 Gy in one LDR fraction. Four hundred and twenty seven patients were enrolled in this noninferiority trial designed with the primary endpoint of vaginal recurrence. The research question was whether vaginal brachytherapy was as effective at controlling vaginal recurrence as external beam, with fewer toxic effects and improved quality of life. Secondary endpoints were locoregional recurrence, distant metastases, and overall- and disease-free survival, and quality of life. At a median follow-up of 45 months the estimated 5-year vaginal recurrence rates were 1.8% for brachytherapy alone and 1.6% for external irradiation. The nodal failure rate was significantly different at 3.8% for the brachytherapy-alone arm and 0.5% for external beam irradiation. Distant metastases, disease-free survival, and OS were similar in both arms. Eighty percent of the patients had deeply invasive disease, and over 90% had grades 1 or 2 disease. In fact, with pathologic review, the 48% who were enrolled as grade 1 disease increased to 78.6% of the study population. Final pathology reviewed revealed that 14% of the patients did not fit pathologic eligibility for the trial, but by report, the outcome was unchanged with these patients excluded. It should not be a surprise that vaginal external beam controlled the vaginal recurrence rate as well as vaginal brachytherapy, especially if the patients were even more low risk than intended. In addition, it is not surprising that the pelvic failure rate was low given the relatively low-risk nature of this population. Gastrointestinal toxicity and quality of life were significantly improved in the vaginal brachytherapy arm compared to the external arm (302, 303). The currently enrolling PORTEC 3 trial randomizes high-risk patients between external irradiation alone and external irradiation with concurrent and adjuvant chemotherapy. The patients eligible for PORTEC 3 include patients with Stage IB grade 3 with lymphovascular space invasion, IC grade 3, Stages IIIA-C, or Stage IB-III with papillary serous/clear cell.

The ASTEC/EN.5 trial was actually two trials with separate randomizations combined as one intergroup trial between the United Kingdom Medical Research Council (MRC) and the National Cancer Institute of Canada (NCIC) (175). This trial examined women with IA grade 3 disease and all grades of IB, and stages I or II papillary serous or clear-cell carcinoma. A lymph node dissection was not required and positive cytology was not an exclusion criteria. Positive pelvic nodes were allowed in the ASTEC trial. Patients were randomized to external beam radiation or observation, although vaginal brachytherapy was at the institution's choice, even in the observation arm. The primary outcome measure was OS, and 905 women were enrolled from 112 centers and 7 countries. With a median follow-up of 58 months there was noted to be no statistical survival difference between the two arms, and the site of the first failure was distantly in both arms, approximately 7%. The vaginal and pelvic failure rates were 3.7% versus 1.5% and 2.6% versus 1.1% for observation (with 53% receiving cuff therapy) and pelvic irradiation, respectively (175).

Despite the fact that adjuvant radiation consistently significantly improved locoregional control, most of the debate focuses on the lack of improvement in OS. Obviously, the endpoint of OS is the gold standard for any randomized trial in cancer, but when dealing with early-stage EC, the data should be interpreted with caution. First, in GOG 99, the primary endpoint was not OS but rather PFS, which was significantly better in the radiation arm (121). Second, because of the relatively high incidence of other comorbidities such as hypertension, DM, and obesity as well as other cancers, the chance of dying from an intercurrent illness is as high, if not higher, than dying from EC. In the radiotherapy (RT) arm of the PORTEC trial (127), the 8-year mortality rate from EC was 9.6% compared to 14.4% from other causes and 5.3% from other cancers. In the no-RT arm, the corresponding rates were 7.5%, 10.6%, and 5.3%. Similar data that emerged from GOG 99 were that approximately half of the

deaths were due to causes other than EC or treatment. This led the authors of GOG 99 to state the following: "With this number of intercurrent deaths in both arms, even if RT reduces the risk of EC-related deaths, the size of this trial is not adequate to reliably detect an OS difference." Thus, it is clear that the competing causes of death in this group of patients who have a low mortality rate to start with make OS a very elusive endpoint to attain. Third, even in patients who die from EC, the most common cause is distant rather than local relapse. In the PORTEC trial, the 8-year mortality rate from local versus distant relapse was 1.1% and 7.9%, respectively, in the RT group, and 2% and 5.2% in the surgery-alone group (127). In the PORTEC 2 trial, vaginal control was the endpoint, but OS was the endpoint in the ASTEC/EN.5 trial (128, 175). In the PORTEC 2 study, 62% and 48% died from intercurrent disease in the external and brachytherapy arms, respectively, and 38% versus 52% died of endometrial carcinoma in the irradiation arm and brachytherapy arm, respectively. In the ASTEC/EN.5 trial, 36% of the deaths were felt not to be disease or treatment related. Therefore, it is unrealistic to expect a local treatment modality such as radiation to alter this pattern of relapse. Note that in the GOG 99 and PORTEC I trials, most of the patients did not have poor prognostic features, thus making it difficult to demonstrate any survival advantage to adjuvant radiation. In PORTEC 2 most (80%) of the patients had deeply invasive carcinoma, but grade 3 deeply invasive tumors were excluded from the trial. In the ASTEC/EN.5 trial, 75% were deeply invasive, but 65% were grades 1 or 2. When the impact of adjuvant radiation in GOG 99 was assessed in the subset of patients with high-risk features (based on age, grade, depth of myometrial invasion, and presence of lymphovascular invasion), the death rate was somewhat lower in the radiation arm (RH, 0.73; 90% confidence interval [CI], 0.43–1.26). The PORTEC 2 study included higher risk patients than PORTEC 1, but was powered as a noninferiority study examining the utility of vaginal brachytherapy to prevent local recurrences. Lee et al., in their analysis of the SEER data, also showed an OS advantage to pelvic radiation for patients with IC grade 1 and grade 3/4 ($p < 0.001$) EC over those treated with surgery alone in their examination of over 21,000 patients. This survival advantage of adjuvant pelvic radiation was significant even in patients who had surgical lymph node staging (304). All of these issues need to be considered when assessing the benefit of adjuvant radiation. Such debate is not new in the field of oncology, but it is important to note that other oncologists treating cancers of the breast or rectum, to name a few, when faced with similar results from prospective, randomized trials, have recognized the importance of a multimodality approach in achieving local and regional control as well as survival.

Type of Radiation

There are two types of radiation (intravaginal brachytherapy or pelvic external beam radiation) that could be used either alone or in combination for early-stage EC. Over the last three decades, the debate about the type of radiation to use has undergone a full circle. In the 1970s and mid-1980s, there was a shift from intravaginal brachytherapy alone to pelvic radiation plus intravaginal brachytherapy. Then, in the late 1980s and early 1990s, there was a shift toward pelvic radiation alone. More recently, and with the increase in surgical lymph node staging, there has been resurgence in the use of intravaginal brachytherapy alone. A recent article by Patel et al. documented this by probing the SEER data base examining the treatment of FIGO Stage I and II endometrial carcinoma over the years 1995–2005 (305). They examined the treatment of 9815 patients and found that the proportion of those receiving vaginal brachytherapy alone increased from 12.9% to 32.8% as the use of external beam alone decreased from 56.1% to 45.7% over the same time

period. The use of both modalities together also decreased from 31.0% to 21.4% as well.

Intravaginal Brachytherapy Alone or Combined With Pelvic Radiation. In a historically important trial, Aalders et al. (306) reported on 540 patients with Stage IB–IC EC who underwent TAH/BSO without lymph node sampling, and postoperative intravaginal brachytherapy to 60 Gy to the vaginal mucosa. The patients then were randomized to observation ($n = 277$) or to supplemental pelvic radiation to 40 Gy ($n = 263$). A significant reduction in local recurrence rates was seen with the addition of pelvic radiation (1.9% vs. 6.9%; $p < 0.01$). With regard to OS, there was no significant difference between the two arms of the study, but in the subset of patients with grade 3 disease and deep myometrial penetration, there was a survival advantage (cause-specific survival) of 18% versus 7% in favor of the pelvic radiation arm (306). The data from this trial contributed to the shift in treatment policy from intravaginal brachytherapy alone to external beam pelvic radiation with or without a brachytherapy boost. As outlined above, in the ASTEC/EN.5 trial over 50% of the observation arm received vaginal brachytherapy as well. Given that this is the most common site of pelvic failure, and the low morbidity of this modality, this paradigm is becoming more common. Greven et al. (307) reviewed the experience of two institutions in order to compare the outcome of the two approaches. In that study, there were 270 patients with Stage I–II EC: 173 were treated with postoperative pelvic radiation alone and 97 with a combination of intravaginal and pelvic radiation (307). The corresponding 5-year pelvic control and DFS rates were 96% versus 93% ($p = 0.32$) and 88% versus 83% ($p = 0.41$). This study as well as others called into question whether the addition of vaginal radiation is needed (308–310). Some studies suggested increased toxicity with the combined approach (308). A recent examination of the SEER database examined 3395 EC patients with stages IA, IB, and II disease. Most patients (62.7%) received external beam alone, and 37.3% received both external and brachytherapy. It was noted that the addition of brachytherapy did not statistically improve survival. A number of other reports (311, 312), however, suggest that vaginal vault radiation can be added to pelvic radiation with minimal morbidity and a very low rate of recurrences. Some institutions choose to treat to 45 Gy plus a brachytherapy boost, and others choose 50.4 Gy without a boost unless higher risk features exist, such as close or positive vaginal margins, extensive lymphovascular space invasion, or cervical involvement. As chemotherapy becomes increasingly common as part of the treatment paradigm, the former regimen may spare more bone marrow and bowel. Given that in all randomized studies thus reported (GOG 99, PORTEC 1 and 2, and ASTEC/EN.5), the vaginal recurrence rate with irradiation ranges between 1% and 2%; any study to examine whether brachytherapy should be added to external beam radiotherapy would require far too many patients than the question warrants.

Intravaginal Brachytherapy Alone. With the increase in surgical lymph node staging, the use of postoperative intravaginal brachytherapy alone regained its appeal, the rationale being that full surgical lymph node staging could potentially eliminate the need for pelvic radiation, whereas vaginal brachytherapy could still address the risk of vaginal cuff recurrence, as demonstrated in PORTEC 2. Several additional reports in the past 10 years also demonstrated a very low rate of recurrence either in the vagina or in the pelvis with such an approach (118, 176, 313, 314).

From the above discussion, it is clear that the options available for patients with early-stage endometrioid EC are numerous. Perhaps it is better to consider different options based on the following factors identified as risk factors for recurrence – age, grade, depth of invasion, lymphovascular space invasion, histology – and consider as well if a nodal dissection was accomplished.

Cancer Limited to the Mucosa (Formerly Stage IA, Grades 1 and 2)

The risk of pelvic lymph node positivity (54) is $\leq 3\%$, and the 5-year PFS rate in this group is of the order of 95% to 98%. It is unlikely that postoperative pelvic external beam radiation would add anything to the final outcome (311, 315). The role of intravaginal radiation in these patients is also of questionable benefit because of an almost negligible risk of vaginal recurrence with surgery alone. Straughn et al. reported no vaginal recurrence in 103 patients with Stage IA grade 1,2 treated with surgery alone (288). This is no longer a discreet stage in the 2010 FIGO staging system.

Cancer Limited to the Mucosa, Grade 3

In GOG 33, there were only eight patients with Stage IA grade 3 disease, making it difficult to draw any meaningful conclusion (55). There were no relapses in the three patients receiving postoperative radiation as compared with one failure in the five patients who received no postoperative therapy. The risk of lymph node metastasis in this group of patients is negligible. Straughn et al. reported on eight patients with Stage IA grade 3 disease treated with surgery alone, with two of the patients developing isolated vaginal recurrence (288). Again this subgroup is not formally staged in the new FIGO staging system, and observation is often favored unless other high-risk features exist such as advanced age, papillary serous or clear-cell variants, or extensive disease.

Low Risk—Stage I A, B Grades 1,2. The outcome of patients who have lymph node dissection and no adjuvant radiation seems to be very good based on prospective (GOG99) and retrospective series. Straughn et al. reported on 296 patients with IB grade 1,2 and found only nine (3%) vaginal recurrences and one (0.3%) pelvic recurrence (288). Horowitz et al. reported on 62 patients who had surgical lymph node staging and received adjuvant intravaginal brachytherapy. There was one (1.6%) vaginal recurrence and no pelvic recurrence (313). In comparison, data published by Alektiar et al. reported on 233 patients with IB grade 1,2 showed a vaginal recurrence rate of only 1% and pelvic recurrence of 2% using postoperative intravaginal brachytherapy alone without routine surgical lymph node staging (316). In addition, Sorbe et al. reported on 110 patients without retroperitoneal lymph node sampling with IB grade 1,2 who were part of a prospective, randomized trial evaluating two different intravaginal brachytherapy doses; the rate of vaginal recurrence was 0.9% and the rate of pelvic recurrence was 1.8% (317). These patients also often fit the GOG 99, PORTEC 1, and PORTEC 2 trials, with or without lymphadenectomy. Thus, it seems reasonable to suggest that either observation or intravaginal brachytherapy (irrespective of surgical staging) is a reasonable option. But when deciding on whether adjuvant radiation is needed, it is important to address three issues. First, older patients tend to have higher rates of relapse. In the study by Straughn et al., eight of the ten vaginal/pelvic recurrences were in patients ≥ 60 years old (288), which was confirmed in the randomized trials. Second, patients with lymphovascular invasion (LVI) have a higher chance of vaginal recurrence as demonstrated by Mariani et al. (291) who reported on 508 patients with Stage I EC treated with surgery alone (152 out of 508 were Stage IA). The presence of LVI increased the vaginal relapse rate from 3% to 7% ($p = 0.02$) as was confirmed by the GOG 99 trial among others. Recent publications of high intermediate and high-risk Stage I–III endometrial carcinoma patients suggest LVSI to be an independent prognostic factor for relapse and survival (285, 318). Third, often the indications for adjuvant radiation are rather arbitrarily based on the amount of myometrial invasion defined in thirds and on whether the tumor is grade 1 versus 2. Yet the amount of myometrial invasion in this group of patients and whether an endometrial cancer

is assigned as grade 1 as opposed to 2 in general do not appear to be significant predictors of outcome (319, 320). It is reasonable to offer patients with IA grades 1 and 2 without LVI and less than 60 years old observation or intravaginal radiation while those with LVI or ≥ 60 years old are offered intravaginal radiation. Those patients that fit the HIR group from GOG 99 are offered the open GOG 0249 trial (≥ 70 with one risk factor, ≥ 50 with 2, or any age with 3 high-risk factors. Factors considered high risk are more than 50% invasion, grade 2 or 3, and lymphovascular space invasion). It is worth noting here that the most likely area of recurrence is the vaginal vault, and brachytherapy is a low morbidity treatment. When that is taken into consideration, if one is undecided whether to offer brachytherapy, remember that it is a far less intensive treatment than treatment of recurrent disease.

Intermediate to High-Intermediate Risk Stage IB Grade 3 to IC Grades 1, 2, 3, Stage II

Up until the last 10 years, most data in the literature on this group of patients were based on pelvic radiation either alone or in combination with intravaginal brachytherapy (309, 311). Since 1988 and the increase in surgical lymph node staging in the United States, a shift occurred with regard to the role of radiation for Stage IB grade 3 and even in Stage IC disease. For some time the treatment decision between whole pelvis radiotherapy and cuff brachytherapy alone was primarily based on whether the patient had surgical lymph node staging. If the decision is made that a node dissection is necessary, and that has recently been called into question for all early-stage patients, an adequate lymph node sampling/dissection should, at a minimum, meet the GOG guidelines of sampling the obturator, external iliacs, internal iliacs, common iliacs, and paraaortic lymph node stations, and the minimum number of nodes sampled should be ≥ 10 .

Surgically Staged Patients. For patients with Stage IB grade 3 disease the retrospective data on intravaginal brachytherapy alone after surgical staging were encouraging (Table 22.14). The average rate of vaginal recurrence and pelvic recurrence was reported as 1.3% for both. This compares favorably with the data from the PORTEC I trial where the 5-year rates for vaginal and pelvic recurrence, in the subset of patients with Stage IB grade 3 disease treated with pelvic radiation ($n = 35$), were 0% and 3%, respectively. A multi-institutional review of 220 patients with Stage IC EC by Straughn et al. compared adjuvant radiation to no radiation in patients with negative nodes on surgical staging (289). The investigators concluded that adjuvant radiation is not needed even though the 5-year DFS was 74.5% for those treated with surgery alone compared to 92.5% for those treated with adjuvant radiation ($p = 0.0134$). It is unlikely that observation alone, even in those patients with full surgical staging, will be the best approach when cuff brachytherapy carries low

Table 22.15 Outcome for IC Endometrial Cancer Grade 1–3 after Surgical Lymph Node Staging and Intravaginal Radiation Therapy Alone

Study	No. of Patients	Median F/U	Vaginal rec	Pelvic rec
Horowitz (2002)	50	65 mo	2% (1/50)	4% (2/50)
Rittenberg (2003)	53	32 mo	0%	1.8% (1/53)
Solheim (2005)	40	23 mo	0%	0%
Alektiar (2007)	40	46 mo	5% (2/40)	2.5% (1/40)
Total	183	—	1.6% (3/183)	2.1% (4/183)

F/U, follow-up; rec, recurrence.

morbidity and can greatly decrease the 18% statistically significant difference in DFS from a retrospective study in which most likely those patients with the worst prognostic features were the ones who received radiation.

Several investigators have shown the feasibility of such an approach, with an average vaginal recurrence rate of 1.6% and pelvic control rate of 2.1% (Table 22.15). Thus, intravaginal brachytherapy alone after surgical staging in patients with IB grade 3 and IC EC seems to provide better local/regional control than surgery alone and, in a properly selected patient population, very few pelvic failures (121, 313, 321, 322). In patients that fit the GOG HIR criteria the appropriate treatment may be determined by the open trial GOG 0249 which randomizes this population between cuff brachytherapy followed by chemotherapy (carboplatin/paclitaxel for 3 cycles) or pelvic radiotherapy (IMRT or 3Dconformal) plus an optional cuff brachytherapy boost for high-risk features. Note that lymph node dissection is optional in this trial. In addition, while lymph node dissection is not allowed, further information may be gained by the PORTEC 3/EN.7 trial, which is randomizing (1988 staging) Stage IB grade 3 with LVSI, Stage IC or IIA grade 3, Stage IIB, Stage IIIA or IIIC, or stages IB–III serous or clear-cell endometrial carcinomas between pelvic radiotherapy alone to 48.6 Gy and the same pelvic radiotherapy with two cycles of concurrent cisplatin plus 4 adjuvant cycles of carboplatin/paclitaxel. In the PORTEC trial, the cuff boost is given with cervical invasion. In the absence of hard data, the risks of pelvic failure must be gauged and determination made if they are sufficient to undergo the risk of pelvic therapy versus vaginal cuff therapy alone. Useful in this regard is the PORTEC trial for Stage IC grade 3 tumors. These 99 patients were not randomized, but were followed prospectively, and all received pelvic irradiation. Again, no lymph node evaluation was done. The locoregional recurrence rate in this high-risk group of patients, without a node dissection, was 12%, with only 5% vaginal, despite adjuvant irradiation. Note that papillary serous and clear-cell were not identified separately in this trial so the percentage of these high-risk pathologies is not known, and given the very high distant failure rate, 31%, this is noted to be a very high-risk group (138).

With the publication of the two randomized trials, ASTEC and CONSORT, questioning the benefit for lymphadenectomy, many gynecologic oncologists in the United States have chosen to evaluate the nodes only in those patients most at risk for metastatic disease—deeply invasive, high-grade, high-risk histology, older patients, and those with lymphovascular space invasion or a combination of factors. Examining the trials where routine lymphadenectomy is performed demonstrates the risk for all Stage I patients to be approximately 10% (55, 131, 132), but

Table 22.14 Outcome for Stage IB Grade 3 Endometrial Cancer after Surgical Lymph Node Staging and Intravaginal Radiation Therapy Alone

Study	No. of Patients	Median F/U	Vaginal rec	Pelvic rec
Fanning (2001)	21	52 mo	0%	0%
Horowitz (2002)	31	65 mo	0%	0%
Alektiar (2007)	21	46 mo	4.8% (1/21)	4.8% (1/21)
Total	73	—	1.3% (1/73)	1.3% (1/73)

F/U, follow-up; rec, recurrence.

selecting the patients at highest risk for disease, while it may not change survival, can certainly guide further treatment paradigms.

No Surgical Lymph Node Staging. In those patients with combinations of high-risk features such as grade 3, high-risk histologies, LVSI, advanced age, and deep myometrial invasion, intravaginal brachytherapy may not be adequate therapy. In the Aalders et al. randomized trial, the rate of local recurrence in the subset of patients with IB grade 3 to IC was 9.3% (13 of 137) for those treated with brachytherapy alone compared to 1.3% (2 of 146) for those treated with brachytherapy and external radiation (306). This is not surprising since no lymph node sampling was done in that trial. Weiss et al. reported on 61 patients with Stage IC EC who were treated with postoperative pelvic radiation alone. With a median follow-up of 69.5 months, there was only one recurrence in the pelvis (1.6%). Their review of the published data from the literature on patients with Stage IC showed a pelvic recurrence of 1.04% in 240 patients treated with pelvic radiation alone compared to 0.97% in 301 patients treated with pelvic and intravaginal radiation. Their conclusion was that pelvic radiation alone is sufficient, and efforts should focus instead on trying to reduce the risk of distant relapse in this group of patients (323). In addition, the results of the GOG 0249 and PORTEC 3 trial may help us segregate these patients into low risk, who may be appropriate for observation or cuff brachytherapy alone, or high risk, who may need more aggressive therapy, including a combination of irradiation and chemotherapy.

Stage II. It is important to recognize the distinction between gross and occult cervical involvement in EC. Gross cervical involvement increases the risk of parametrial extension as well as spread to pelvic LN in a fashion similar to primary cervical cancer. Patients with gross cervical involvement from EC could undergo radical hysterectomy and pelvic lymph node dissection or preoperative radiation including pelvic radiation and intracavitary brachytherapy followed by simple hysterectomy. For occult cervical involvement, the treatment often consists of simple hysterectomy with or without lymph node surgical staging and adjuvant radiation. The type of radiation most often utilized is pelvic radiation and intravaginal brachytherapy. Pitson et al. reported on 120 patients treated with such a combination (324). The 5-year DFS rate was 68%, and the rate of pelvic relapse was 5.8% (7 of 120).

There are also emerging data on the role of intravaginal brachytherapy alone in patients with occult cervical involvement who also had surgical lymph node staging. The rate of pelvic recurrence in four such series ranged from 0% to 6%, but the data need confirmation on a larger number of patients and longer follow-up (313, 325, 326). Another important distinction to make in Stage II EC is the difference between glandular versus stromal invasion. The new staging system now combines these two entities into Stage II and does not make the distinction (79). Intravaginal brachytherapy alone could be used for surgically staged patients with mucosal involvement alone (313, 327), whereas those with disease invading into the stroma, with close margins or with a significant amount of cervical disease, should be treated with pelvic radiation with or without intravaginal brachytherapy boost until trial results demonstrate a better option.

Advanced-Stage Disease

Radiation

The outcome of patients with isolated adnexal involvement (Stage IIIA) treated with pelvic radiation is fairly good, although the studied patient numbers are small. Connell et al. reported on 12 patients treated with postoperative pelvic radiation with a 5-year DFS of 70.9%. The weighted average of 5-year disease-free and OS rates from literature review in that study were

78.6% and 67.1%, respectively (328). Patients with isolated serosal involvement (Stage IIIA) do worse than those with isolated adnexal involvement. Ashman et al. reported on 15 patients with isolated serosal involvement who were treated with pelvic radiation (329). The 5-year DFS was only 41.5%. If pelvic node involvement (IIIC1) is the only major risk factor, treatment with postoperative pelvic radiotherapy can yield a 60% to 72% long-term survival rate in these patients (141, 330, 331), but distant failure is a problem that new trials evaluating chemotherapy will hopefully change. Patients with Stage IIIC2 disease, by virtue of paraaortic node involvement, represent a particularly high-risk group. Following surgery, these patients are generally treated with extended field radiation to encompass the pelvis and the paraaortic regions. With this aggressive approach, several investigators have reported 30% to 40% survival rates in small patient populations (332). The question of whether it is safe to omit radiation even after adequate surgical lymph node staging in patients with IIIC2 EC was addressed in a study from the Mayo Clinic. Mariani et al. reported on 122 patients with node-positive disease; at 5 years the risk of pelvic recurrence was 57% after inadequate lymph node dissection and/or no RT compared to 10% with adequate lymph node dissection (>10 pelvic nodes and ≥ 5 paraaortic nodes) and radiation. This difference was statistically significant on univariate ($p < 0.001$) and multivariate analysis ($p = 0.03$), indicating the need for postoperative radiation even after adequate surgical staging (174). The recognition that a significant number of patients with Stage III disease fail in the abdomen (291, 330) has prompted a number of investigators to evaluate whole abdominal radiotherapy in these patients (333, 334) and after a small GOG trial a randomized trial was undertaken (335).

Chemoradiation

In the GOG 122 trial, there were 396 patients with Stage III and optimally debulked Stage IV disease who were randomized to whole abdomen radiation ($n = 202$) or to doxorubicin-cisplatin chemotherapy ($n = 194$). With a median follow-up of 74 months, there was significant improvement in both progression-free (50% vs. 38%; $p = 0.007$) as well as OS (55% vs. 42%; $p = 0.004$), respectively, in favor of chemotherapy (262). To elucidate the right approach for these patients, however, a closer look at these data is warranted. First, the overall absolute rate of relapse was 54% in the radiation arm compared to 50% in the chemotherapy arm, a small difference if any, yet the corresponding 5-year PFS rates were 38% and 50% ($p = 0.007$), respectively. Why the discrepancy? The answer is that the 5-year PFS rate for the radiation arm was 38% while the chemotherapy arm has two separate 5-year rates. The first one, called unadjusted, was 42%, which is not that significantly different from the 38% rate with radiation, and the second, called “adjusted for stage,” was 50%, which was significantly different from the radiation arm. This led us to the second issue: Was the adjustment for stage warranted? The answer is no. Numerically, there were more patients with lymph node involvement in the chemotherapy than the radiation arm, but having positive LN was not an independent predictor of poor outcome in this study. Therefore, the adjustment was not warranted, and if any adjustment was needed, it should have gone to the radiation arm since there were more patients with positive cytology in this arm, a factor with a HR of 1.8 (95% CI, 0.89–1.55) in predicting poor outcome. Third, what should be made of the significant difference in OS? There were 15 deaths unrelated to EC or protocol treatment in the radiation arm compared to only 6 in the chemotherapy arm, raising a question about whether the two arms of the study were truly balanced. Finally, the pelvic recurrence rate was lower in the radiotherapy arm, which indicates that perhaps both modalities could be used for the advantages they provide – locoregional control for irradiation and distant control for chemotherapy. Another randomized trial comparing adjuvant radiation to chemotherapy

(doxorubicin-cisplatin-cyclophosphamide) in patients with Stage I–III was recently reported and showed no difference in outcome between the two arms (387). With a median follow-up of 95.5 months, the 5-year DFS was 63% in both arms ($p = 0.44$) and the 5-year OS rates were 69% in the radiation arm compared to 66% in the chemotherapy arm ($p = 0.77$). What those two trials show is that chemotherapy at a minimum is equivalent to radiation in this group of patients and ought to be used, not alone, but rather in combination with radiation. Greven et al. reported the results of Radiation Therapy Oncology Group (RTOG) 9708 on 44 patients with Stage I–III EC who were treated with pelvic radiation and intravaginal brachytherapy given concurrently with cisplatin 50 mg/m² on days 1 and 28 of radiation followed by four cycles of cisplatin (50 mg/m²) and paclitaxel (Taxol) (175 mg/m²). The 4-year disease-free and OS for those with Stage III disease (66% of patients) was 72% and 77%, respectively (336).

As the follow-up study to GOG 122, GOG 184 was launched. The combination of irradiation and chemotherapy was used to control disease and was done in a sequential fashion to limit toxicity. Five hundred and fifty two Stage III and IV patients were enrolled (after 66 patients were enrolled, those with upper abdominal disease were excluded) and received tumor volume directed irradiation (51% received 5040 cGy pelvis irradiation alone, and 49% received 4320–4350 cGy of extended field for positive paraaortic disease, or undissected paraaortics) and were then randomized to cisplatin/adriamycin or cisplatin/adriamycin/paclitaxel (337). Growth factors were allowed and 80% of the patients were able to complete the assigned chemotherapy regimen following full dose radiotherapy. The locoregional recurrence rate (any failure in the pelvis, vagina or paraaortics as first failure) was 10%, which compares favorably with GOG 122 (isolated failures: 13% in WAI arm and 18% in chemotherapy arm), Greven's (187) study of 105 irradiated patients with IIIC disease with a pelvic failure rate of 21%, and Mundt's two series; one that described 30 patients with Stage IIIC treated with postoperative pelvic irradiation with an infield failure rate of 23%, and a second trial of 43 high-risk Stage I–IV endometrial carcinoma patients treated with chemotherapy alone who experienced a 21% actuarial rate of pelvic recurrence as their first or only site of recurrence (338, 339). The distant failure rate in these trials was unacceptably high, ranging from 26% to 55%. The PORTEC 3 trial described above and the open GOG 0258 address treatment in this advanced population. In the GOG 0258 trial, stages III or IVA are randomized between volume directed postoperative irradiation with concurrent cisplatin followed by 4 cycles of carboplatin/taxol or 6 cycles of carboplatin/taxol alone.

SPECIAL SITUATIONS

Positive Cytology Without Adnexal or Serosal Involvement

In this subset of patients, the presence of other adverse features such as aggressive histologies or deep myometrial invasion should be determined first as this is noted but no longer part of the official staging system. The argument to remove it from the staging is that without other factors, cytology alone has unclear prognostic value (340). The literature regarding the benefits of treatment in this setting is mixed; even if treatment is beneficial, the appropriate modality still has to be defined. Based on the concept that the entire peritoneal cavity is at risk, intraperitoneal radioactive colloidal ³²P had been used by some with results that were better than in historic controls (341), but carries significant toxicity. Eltabbakh et al. reported on 27 patients with FIGO grade 1,2

and <50% myometrial invasion who were treated with intra-vaginal brachytherapy and megestrol acetate (Megace). None of the patients relapsed or died from their disease. Megace was given for 1 year, and at the end of therapy, 24 patients underwent second-look laparoscopy and peritoneal cytology. In 23 patients, the cytology was negative, and the remaining patient with persistent positive cytology received an additional year of Megace after which cytology was confirmed to be negative (342). Given this, as an isolated risk factor, vaginal brachytherapy with Megace is likely the only radiation regimen to be recommended.

Definitive Radiation for Inoperable Disease

Patients with medically inoperable Stage I–II uterine cancer are usually treated in a fashion similar to those with cervical cancer by using intracavitary applicators with or without pelvic radiation. For patients with clinical Stage I grade 1 or 2 and no or minimal evidence of myometrial invasion or lymph node metastasis on MRI, intracavitary brachytherapy alone may be sufficient provided the uterus is of such a size and shape that it can be fully covered with the brachytherapy irradiation. There are several applicator choices with one or two tandems (depending on uterus size) and either a cylinder or ovoids. The American Brachytherapy Society Guidelines have recommended either dosing in the uterus 2 cm from the tandem, and treating the upper several cm of vagina, or, in the age of image guidance, dosing to the uterine serosa (343). When pelvic radiation is added to brachytherapy, the dose is usually 45 to 50 Gy supplemented with intracavitary brachytherapy. Rouanet et al. (344) treated 250 patients with endometrial cancer using LDR brachytherapy, which yielded a 5-year disease-specific survival of 76.5%. An alternative brachytherapy approach would be to use the Hymen or Simon afterloading system, which consists of multiple Teflon tubes that are inserted into the uterine cavity. With such a treatment approach, Grigsby et al. (345) reported that the 5-year PFS rate of patients with clinical Stage I disease treated with a combination of external and intracavitary radiotherapy was 94% for grade 1 disease, 92% for grade 2 disease, and 78% for grade 3 disease. High-dose-rate brachytherapy is increasingly used and demonstrates equivalent control (346). Nguyen (346) and Niazi (347) reported on patients with clinical Stage I–II disease treated with HDR alone or with external irradiation, and the disease-specific survival was 76% at 8 years, and 91% at 15 years, respectively. Note that many of these patients, by virtue of being medically inoperable, will die of other causes than their early-stage uterine carcinoma. Intriguingly, Fishman published a study comparing the operable with the inoperable and found that those inoperable patients who did not die of intercurrent disease had a similar median 5-year survival (348). Kucera et al. studied a larger population of 228 and using HDR alone found a disease-specific survival of 85% at 5 years and 75% at 10 years (349). For several of these studies, image guidance was not available, and the expectation is that dosing the radiation in the appropriate area will increase control and disease-specific survival. Although uncommonly seen, Stage IIIB patients are definitively treated with irradiation including external beam and intracavitary/interstitial brachytherapy, as they are not surgical candidates (350).

RADIATION THERAPY TECHNIQUES

Intravaginal Brachytherapy

Intracavitary vaginal brachytherapy is designed to deliver dose to the vaginal surface and underlying lymphatic channels at risk

of harboring residual disease. Choo et al. demonstrated that 95% of vaginal lymphatic channels lie within 5 mm of the vaginal mucosa and therefore this modality is well-suited to deliver this dose effectively and more safely than with external beam irradiation (351). Intravaginal brachytherapy can be delivered using LDR to 60 Gy prescribed to the vaginal mucosa or 30 to 35 Gy prescribed to 0.5 cm depth from the vaginal mucosa using either ovoids for the upper several cm of the vagina or a cylinder, which allows the length treated to be tailored to the clinical situation. Very rarely, the whole length of the vagina needs to be treated, and should be considered for those with close or positive margins, extensive lymphovascular invasion, or very high-risk histologies. HDR brachytherapy guidelines have been established and published for dose and fractionation, although the most common is 700 cGy for 3 fractions treated at 5 mm depth according to a survey published by Small et al. (352).

External Beam Radiation

Pelvic Radiation

Most patients are treated in the postoperative setting. At the time of simulation, the small bowel may be opacified using oral contrast, a vaginal marker is used to define the vaginal cuff, and the rectum may be opacified with barium or CT-compatible contrasts. Patients may be placed in the prone position to displace the small intestines from the radiation field or placed on a prone treatment board that allows the abdominal wall and contents to be displaced anteriorly through a hole in the board, to allow displacement out of the pelvis (353). The target volumes are the obturator, external, internal, and lower common iliac nodes, and the proximal two-thirds of the vagina. High-energy linear accelerators (15 MV) are preferred because of their sparing of the skin and subcutaneous tissue when the treatment is a four-field box or when three-dimensional conformal therapy (3DCF) is used. The ideal beam arrangement with the conventional four-field pelvic-box technique places the superior border at L5-S1, the inferior border at the bottom of the obturator foramina or at least 3 to 4 cm below the vaginal apex, and the lateral border 1–2 cm beyond the widest point of bony pelvis. For the lateral fields, the anterior border is in front of the pubis symphysis to allow external iliac coverage and the posterior border covers S1/S2. The superior and inferior borders are the same for the anterior and posterior fields. All fields are treated daily to a dose of 1.8 Gy. A total dose of 50.4 Gy is given to sterilize microscopic disease, or 45 Gy when combined with intravaginal brachytherapy. Three-dimension conformal field (3DCF) therapy uses the same beam arrangement, but a planning CT scan is used to outline both tissues at risk and normal tissues. Blocks are placed based on the contours that allow more accurate targeting and sparing of more normal tissues. Recent evidence demonstrates decreased acute and late toxicity to the bowel when intensity modulated radiation therapy (IMRT) is used (Figure 22.13). Mundt et al. demonstrated a significant reduction in acute and chronic gastrointestinal toxicity when IMRT was compared to conventional radiation (354–357). IMRT, compared to the four-field box or 3DCF therapy, uses the power of computers to shape the radiation dose to tissues at risk of harboring microscopic disease and minimize normal tissue dose. Both 3DCF therapy and IMRT use small collimator “leaves” to finely shape the beam. These “leaves” are mobile and block portions of the generated x-rays. If the collimator “leaves” move while the radiation beam is on and vary the beam intensity, areas of tumor and normal tissue can receive a spectrum of doses, hence the term “intensity modulated.” Papers have been published on the use of IMRT in postoperative uterine and cervical carcinoma, vulvar carcinoma, whole abdominal radiotherapy, vaginal carcinoma, and intact cervical carcinoma. However, because of the daily variation in

bladder and rectal filling, and the resultant mobility of the upper vagina, the use of IMRT should be undertaken with caution, and experience with contouring, planning, and delivery is essential (358, 359). The introduction of new technology such as tomotherapy (a linear accelerator linked to an on-line CT scanner), cyberknife (a linear accelerator capable of fiducial imaging to target radiation), and cone-beam CT (CT scan mounted to the linear accelerator) for image-guided radiotherapy (IGRT) assists in daily target and normal tissue localization. Randomized, prospective data comparing this to traditional therapy are lacking but ongoing trials are evaluating risks, effectiveness, and cost.

Extended Field

This technique is mainly used for patients with documented positive paraaortic nodes or patients at risk of disease but without surgical evaluation. Either 3DCF irradiation or IMRT can be utilized (360). Attention should always be paid to the kidney dose when paraaortic fields are utilized, especially with increased use of chemotherapy in these patients. The lower border is the same as in pelvic radiation, but the upper border is extended in some patients as high as the T12–L1 interspace. The typical dose is 45.0 Gy at 1.8 Gy per fraction or 1.5 Gy per fraction if patients develop acute gastrointestinal toxicity.

Whole Abdomen Radiation (WART)

WART is uncommonly used since the publication of GOG 122. The standard approach is AP/PA open fields with five half-value layer (HVL) kidney blocks placed over the PA field only (if the patient is lying supine) from the start of the treatment. The dose is usually 30.0 Gy at 1.5 Gy per fraction followed by a 19.8 Gy boost to the pelvis at 1.8 Gy per fraction. The upper border is usually placed 1 cm above the diaphragm, and the lateral borders should extend beyond the peritoneal reflections. The lower border is usually at the bottom of the obturator foramen.

Complications of Radiation

Pelvic Radiation

In GOG 99, the risk of Grade 3 or 4 complications was 14% with RT versus 6% without. In the PORTEC I randomized trial (121), the overall (grades 1 to 4) rate of late complications was 26% in the RT group compared to 4% in the observation group ($p < 0.0001$). Most of the late complications in the RT group, however, were grades 1,2 (22%), and only 3% were grades 3,4. It is also important to note that many patients in this trial were treated with AP/PA fields in which the overall rate of complications was 30% compared to 21% for those treated with the four-field box ($p = 0.06$), and even lower for IMRT. The recent 15-year update notes that second malignancies were diagnosed in 16% of the observation patients and 22% of the irradiation patients, a difference that was insignificant. In PORTEC II, grades 1 and 2 gastrointestinal side effects were significantly higher with external beam (delivered using CT planning and with multifield or 3DCF techniques) than with vaginal brachytherapy (53.8% vs. 12.6%), but grades 3 and 4 were not reported, which is curious, suggesting it was very low and likely not significantly different between the arms. Late grade 3 gastrointestinal effects were reported in 2% of those receiving EBRT versus less than 1% in those with VBT. Alternatively, grade 3 atrophy (marked atrophy with or without narrowing or shortening) was reported in less than 1% of those with EBRT and 2% with VBT. There were no grade 4 or 5 toxicities in either arm. In more advanced disease trials, we see a similar pattern. In GOG 122, those with at least one grade 3 and 4 hematologic toxicity between the arms of WART or chemotherapy were 14% versus 88%, respectively.

FIGURE 22.13. Pelvic IMRT demonstrating the sparing of bladder and bowel.

Grade 3 or 4 acute gastrointestinal toxicity was 13% versus 20% in the WART and chemotherapy arms, respectively. Late grades 3 or 4 gastrointestinal or genitourinary toxicity between the arms were 13% and less than 1% for WART, and 20% and 3% for chemotherapy, respectively. Many investigators were surprised that the chemotherapy arm had increased acute and late gastrointestinal effects when compared to WART. Statistical analyses of these results were not reported (262). In GOG 184, where everyone received whole pelvis radiation and 49% received pelvis and paraaortic irradiation, the rate of late grade 3 or higher treatment-related gastrointestinal events was only 5% (337). Acutely pelvic irradiation can cause fatigue, cystitis, diarrhea, skin erythema and breakdown, and vaginitis. Adding a paraaortic field can add nausea and gastritis to the list. VCB is very well tolerated, and complaints during treatment are rare other than discomfort with placement of the device. Late toxicities include intra-abdominal scarring, chronic cystitis or enteritis, bowel obstruction requiring surgery, rectal telangiectasias, and, more unusually, bone weakening with fracture, fistula formation, kidney or spinal cord damage, second malignancies, menopause if the ovaries are in the field, and with WART liver toxicity. With vaginal brachytherapy, vaginal atrophy, narrowing, dryness, and agglutination are possible.

Radiation Therapy for Local Recurrence

Radiation therapy can be curative in a select group of patients with small vaginal recurrences who have not received prior radiation. The 5-year local control rate ranges from 42% to 65%, and the 5-year OS rate from 31% to 53% (361). Creutzberg

et al. reported on survival after relapse from the PORTEC randomized trial (362). In patients who were initially randomized to surgery alone ($n = 46$ out of 360), the 5-year survival after vaginal relapse was 65%. But before adopting salvage radiation as a treatment policy for all early-stage EC, a few aspects of this trial need to be addressed. First, the 5-year survival rate from the PORTEC trial is much higher than what is reported in the literature. Most likely, the vaginal recurrences in this trial were detected very early, unlike patients in the community. The extent and size of local recurrence in EC are very significant predictors of outcome (361). Second, this high rate of salvage pertains only to isolated vaginal recurrence. The rate of survival at 3 years for pelvic recurrence in the PORTEC trial was 0%. Third, although the trial does not mention any data on complications, it is not unrealistic to expect a higher complication rate than what is normally seen with adjuvant radiation. With salvage radiation, external beam RT and brachytherapy are often combined, and the doses of radiation required are much higher than those used with adjuvant radiation. A study from the University of Texas MD Anderson Cancer Center by Jhingran et al. clearly highlights these issues (363). They reported on 91 patients who were treated with definitive radiation for isolated vaginal recurrence. The 5-year local control and OS rates were 75% and 43%, respectively. The median dose of radiation was 75 Gy, which often included external radiation and brachytherapy. The rate of grade 4 complications (requiring surgery) was 9%. Thus, when talking with a patient about adjuvant radiation versus radiation reserved for salvage, these issues need to be addressed and compared to the excellent local control and low morbidity obtained with adjuvant irradiation. The currently open GOG 0238 trial randomizes patient with recurrence of endometrial carcinoma limited to the pelvis and vagina to concurrent cisplatin/irradiation versus standard irradiation alone.

SYSTEMIC THERAPIES

Endocrine Therapy

Hormonal agents have been found to be valuable, particularly in the patient with recurrent disease, and reviews of their use have been extensively published. Response rates to a variety of endocrine agents, including progestins, antiestrogens, and aromatase inhibitors are presented in Table 22.16 (364–369). The overall response to progestins is approximately 25%. However, some trials demonstrate lower response rates, usually in the range of 15% to 20%. These studies generally used more rigorous response criteria and had multi-institutional participation. A higher dose of progestin does not appear to increase the response rate. In one randomized trial of 200 mg/d versus 1,000 mg/d of

Table 22.16 Response to Endocrine Therapy

Hormonal Agent	References	Average Dose	Response Rate (%)	Range (%)
Hydroxyprogesterone caproate (Delalutin)	(464,465)	1–3 g IM q wk	29	9–34
Medroxyprogesterone acetate (Provera)	(462)	200–1,000 mg IM q wk or po qd	22	14–53
Megestrol acetate (Megace)	(465)	40–800 mg po qd	20	11–56
Tamoxifen (Nolvadex)	(470,471)	20–40 mg po qd	10	0–53
Goserelin acetate	(486)	3.6 mg SC q mo	11	NA
Anastrozole (SERM)	(469)	1 mg po qd	9	NA
Arzoxifene (SERM)	(466)	20 mg po qd	31	NA

IM, intramuscularly; NA, not applicable; SC, subcutaneously; SERM, selective estrogen receptor modulator.

medroxyprogesterone acetate (MPA), the overall response rate was actually 25% versus 15% favoring the low-dose arm (370). The time to treatment failure and median OS of the low-dose versus high-dose regimens, respectively, were 3.2 versus 2.5 months and 11.1 versus 7.0 months, all showing no advantage for an increased dose. Prognostic factors related to response were performance status, grade, and progesterone receptor (PR) level. The response rate was only 8% in poorly differentiated tumors. A phase 2 trial of high-dose megestrol (800 mg orally daily) in 63 patients was associated with a response rate of 24% overall, which is similar to lower-dose regimens with doses of 40 mg po qid. As in the majority of studies with hormonal agents, response rates were statistically higher in patients with grade 1 or 2 lesions (37%) versus grade 3 lesions (8%); $p = 0.02$. In addition to grade, a long DFS (exceeding 2 or 3 years) and positive estrogen or PR status have all been associated with an increased frequency of response (Table 22.17) (364, 367, 370). Age, location of metastatic disease, number of metastatic sites, prior therapy, and weight have also been analyzed by several investigators, but they have not been convincingly linked with response.

Tamoxifen has been investigated in patients with recurrent disease in several studies (369, 370). Results have varied, but in general, response rates have been modest in untreated patients. A GOG study evaluated 68 patients with advanced or recurrent disease receiving tamoxifen at 20 mg po bid and showed an overall response rate of 10% (90% CI, 5.7–17.9). The median PFS was short at 1.9 months (90% CI, 1.7–3.2 months) and the OS was 8.8 months (90% CI, 7.0–10.1 months). One small randomized phase 2 study comparing megestrol acetate to megestrol acetate with tamoxifen showed no advantage in response rate for the combination, with response rates of 20% versus 19%, respectively (371). The lack of synergistic response is supported by observations of endometrial carcinoma treated in a nude mouse model. Tumors treated with medroxyprogesterone or tamoxifen plus medroxyprogesterone were devoid of PR during the growth inhibitory and regrowth phase of the tumor resulting

from receptor down-regulation (372). The possibility of alternating tamoxifen with megestrol acetate in order to exploit the recruitment of PRs by tamoxifen is an interesting strategy. The GOG performed a phase 2 study with 56 patients with advanced or recurrent EC who had not previously received chemotherapy or hormonal manipulation (373). Patients were treated with megestrol acetate at 160 mg/d for 3 weeks alternating with tamoxifen 40 mg po qid for 3 weeks. An overall response rate of 27% (90% CI, 17.3–38.4) with a 21.4% complete response rate was seen, with the duration of response exceeding 20 months in 8 of 15 responders. The response rate was 38% for patients with grade 1 disease and 22% for those with grade 3 disease. In another phase 2 GOG study, a similar patient population was treated with tamoxifen 40 mg po daily plus alternating weekly cycles of medroxyprogesterone acetate 200 mg po daily (374). Of the 58 evaluable patients, the response rate was 33% (6 complete, 13 partial). Although these phase 2 results are intriguing, a randomized study would be required to determine if alternating hormones is superior to single-hormone approaches. Positive receptor status has been associated with improved disease-free and OS rates (375, 376). These data indicate that the receptor status provides important biologic information and that receptor-positive tumors tend to be better differentiated and slower growing than their receptor-negative counterparts. Chemotherapy had no effect on hormone receptor capacity in a nude mouse model of xenografted EC. Other factors, such as changes in vaginal cytology during treatment (377), and results in the subrenal capsule chemosensitivity assay (378) and in the nude mouse model (379) may help predict response to progestins.

Several studies have evaluated gonadotropin-releasing hormone analogs in patients with metastatic EC. Gallagher et al. (380) noted one complete and five partial responses to leuprolide or goserelin in 17 patients (35% response; 95% CI, 13%–58%) with metastatic disease. Of note, the duration of remission ranged from 7 to 30 months, and 14 of the 17 patients had been previously treated with progestins. Another report described four responses in seven postmenopausal patients with EC treated with goserelin (381). *In vitro* studies in human EC cell lines have suggested that such growth inhibition may have been due to apoptosis (382). The GOG studied goserelin at 3.6 mg subcutaneously monthly in 40 patients with advanced or recurrent disease. Seventy-one percent of patients had received prior radiotherapy. There were two complete (5%) and three partial (7%) responses with an overall response rate of 11% (95% CI, 4%–27%). Goserelin is felt to have limited activity in this patient population, and no additional single-agent studies are planned (365).

Investigation is under way in patients with uterine cancer to evaluate the activity of SERMs. These agents have ER-antagonist activity in breast and uterine tissues, and ER-agonist activity in bone. The first reported study to date is from the GOG and evaluated anastrozole at 1 mg po daily orally in 23 unselected patients (i.e., 9 patients had grade 2 tumors and 14 patients had grade 3 tumors). A partial response rate of 9% was seen (90% CI, 3%–23%). It is noted that the partial response rate of 9% in this study is similar to the 8% reported in grade 3 patients treated with standard progestins (375). Another study evaluated the investigational SERM arzoxifene in 37 patients. Twenty-six patients were ER positive and 22 were PR positive. A response rate of 31% (95% CI, 25%–51%) was seen in this selected patient population with a median duration of response of 13.9 months (366). Additional study of these agents in patients with well-differentiated tumors is warranted.

Study	Treatment	Grade	N	RR
Podratz (1985)	Various progestins	1	10	40%
		2	71	15%
		3	73	2%
Lentz (1996) (371a)	MA 800 mg/d	1	14	37% (grade 1–2)

Endometrial Cancer and Cytotoxic Chemotherapy

Recent data illustrating the utility of chemotherapy have expanded the role of chemotherapy to include not only metastatic disease but also surgically staged advanced disease. The role of chemotherapy

in the management of high-risk early-stage disease remains investigational and is currently the focus of several clinical trials.

Early-Stage High-Risk Uterine Cancer

Despite the ability for surgical staging to define a low-risk patient population for most patients with negative pelvic and paraaortic LN, certain subgroups of patients with Stage I–II EC have been shown to have a higher risk of recurrence. These patients may benefit from postoperative adjuvant therapy with radiation, chemotherapy, or the combination of the two. In two prospective trials comparing pelvic radiation to chemotherapy, comparable outcomes were seen between the arms (299–300).

Hogberg et al. (383) reported the results of two randomized studies (NSGO-EC-9501/EORTC-55991 and MaNGO-ILIADE-III) examining the role of sequential adjuvant chemotherapy and radiotherapy. The two randomized clinical trials included patients with Stage I–III EC with no residual tumor and prognostic factors consistent with high-risk disease. These patients were randomly assigned to either adjuvant radiotherapy with or without sequential chemotherapy. The authors reported that in the NSGO/EORTC study, the combined modality treatment was associated with a 36% reduction in the risk for relapse or death (HR, 0.064; 95% CI, 0.41–0.99; $p = 0.04$). A similar HR was reported in the MaNGO study (HR, 0.61) but no significant significance was appreciated. In the combined analysis of these two trials, the estimate of risk for relapse or death was similar, with an HR of 0.69 (CI, 0.46–1.03; $p = 0.07$). Careful examination of the two independent studies reveals that the majority of patients in the NSGO-EC-9501/EORTC-55991 trial had Stage I disease

while patients in the MaNGO ILIADE-III had predominantly Stage IIB–IIIC disease. Overall, these results should be interpreted with caution given the heterogeneity of the population studied.

The role of radiation therapy alone or in combination with chemotherapy is currently investigated in the GOG–249, phase III clinical trial that compares the outcomes of pelvic irradiation versus VCB followed by paclitaxel/carboplatin in patients with high-risk early-stage endometrial carcinoma. RTOG 0921 is a phase II trial of postoperative intensity modulated radiation therapy with concurrent cisplatin and bevacizumab followed by four cycles of platinum and taxane.

Adjuvant and Advanced Disease

Chemotherapy for adjuvant and advanced disease has been evaluated in multiple clinical trials. Trials have compared chemotherapy to radiation therapy as well as to other chemotherapeutic regimens. For historical purposes, Table 22.18 highlights a comprehensive list of clinical trials.

The initial combinations to be explored included the use of cyclophosphamide with doxorubicin (384–386) followed by the addition of cyclophosphamide and doxorubicin to cisplatin (CAP) (387–390) and doxorubicin to cisplatin (AP) (391–395). Given the lack of additional benefit with a three-drug combination, the AP regimen became the “standard” to which more contemporary approaches were compared. It is important to note that the majority of these trials enrolled a heterogeneous patient population. Despite the lack of prospective data tailored to individual disease stage, these trials have provided constructive insights to the management of patients with advanced disease.

Table 22.18 Combination Chemotherapy

Chemotherapy versus Radiation Therapy

GOG 122 compared whole abdominal radiation therapy to doxorubicin/cisplatin chemotherapy in patients with *Stage III–IV disease who underwent surgical assessment and had a maximum of 2 cm of disease postoperatively* (262). The results demonstrated an improved PFS and OS in patients with chemotherapy, with the reduction in recurrences largely due to reduced abdominal and distant sites of disease. The Japanese GOG 2033 trial (300) randomized 385 women with *stages IC–III endometrioid adenocarcinomas* to WPR therapy versus chemotherapy using the regimen cisplatin, doxorubicin and paclitaxel. PFS at 5 years was 83.5% versus 81.8 %. However, in a subgroup analysis of patients with Stage IC over the age of 70 with grade 3 endometrioid tumors or Stage II or IIIA, chemotherapy was associated with improvement over pelvic radiation therapy both in terms of PFS (83.8% vs. 66.2%, respectively, $p = 0.024$) and OS (89.7% vs. 73.6 %, respectively, $p = 0.006$).

GOG 184 (337) randomized 552 women with *Stage III disease debulked to a maximum residual of 2 cm or less* followed

by volume-directed radiation therapy to doxorubicin and cisplatin (AP) or doxorubicin/cisplatin and paclitaxel (TAP). At 3 years the proportion of patients alive and free from recurrence was similar (62% AP versus 64% TAP). The overall hazard for recurrence or death of TAP compared to AP was 0.90 (95% CI, 0.69–1.17). In women with gross residual disease at the time of enrollment, TAP was associated with a 50 % reduction in the risk of relapse or death (HR, 0.50; 95% CI, 0.26–0.92).

Chemotherapy

Given the phase II activity of single-agent taxanes (396–398), the GOG conducted a randomized trial (GOG 163) (399) *for patients with primary Stage III and IV or recurrent EC with measurable disease* comparing doxorubicin and cisplatin to doxorubicin with 24-hour paclitaxel and granulocyte colony-stimulating factor (G-CSF). There were no significant differences in response rate (40% vs. 43%), PFS (median 7.2 vs. 6.0 months), or OS (median 12.6 vs. 13.6 months) for arms 1 and 2, respectively.

The disadvantage of GOG-163 was the lack of platinum in the taxane-containing arm. The addition of a taxane was subsequently studied in GOG-177 (400) (*patients with primary Stage III and IV or recurrent EC with measurable disease*). GOG 177 utilized doxorubicin (60 mg/m² or 45 mg/m² in patients with prior radiotherapy) with cisplatin (50 mg/m²) as the standard arm versus paclitaxel (160 mg/m²) with doxorubicin (45 mg/m²) and cisplatin (50 mg/m²) and G-CSF as the investigational regimen. The primary objective was to determine if the addition of paclitaxel improved response rate, and progression-free and OS. Two hundred and seventy-three patients were enrolled, and the study was balanced for history of prior RT (50% vs. 46%), serous carcinoma (15% vs. 19%), stage, grade, and body surface area (BSA). Grade 3 and 4 platelet toxicity was higher in the three-drug arm (21% vs. 2%), but other hematologic toxicity was ameliorated with G-CSF: absolute neutrophil count (ANC) was 36% versus 50%, and neutropenic fever was 3% versus 2%. Nonhematologic grade 3, 4 toxicity was higher in the three-drug arm: gastrointestinal 59% versus 39% and metabolic 25% versus 13%. Response rates were better with the triplet: complete response 22% versus 7%, partial response 36% versus 27%, and overall response rate (RR) 57% versus 34%. Median PFS was 8.3 versus 5.3 months ($p < 0.0005$) and median OS was 15.3 versus 12.1 months ($p = 0.024$). Responses were similar in serous (48%) versus nonserous histology (45%). Overall, paclitaxel doxorubicin cisplatin (TAP) chemotherapy increased 12-month survival to 59% compared to 50% with AP with an HR of 0.75 (0.56 to 0.998). Although the TAP regimen produced an improvement in response rate and PFS, survival was minimally increased, and it is associated with greater toxicity. The combination of paclitaxel and carboplatin as a doublet has also been evaluated in a variety of phase 2 trials and retrospective studies with response rates in the 43% to 80% range (401, 402).

GOG 209, a randomized trial comparing doxorubicin, cisplatin, and paclitaxel (TAP) with carboplatin and paclitaxel (TC), (*Stage III, IV or recurrent disease*) was recently reported. TC was not inferior to TAP in terms of PFS (median PFS of TAP vs. TP: 13.5 vs. 13.3 months; HR, 1.03) and OS (40.3 vs. 36.5 months; HR: 1.05) based on interim analysis results. Overall, the toxicity profile favored TC with less sensory neuropathy (sensory neuropathy > Grade 1: 26% vs. 19%, $p < .01$) (403).

Sequence of Therapeutic Modalities

With the current data in mind, the sequence of therapy in patients with advanced surgically resected disease remains in question. Various approaches have been delineated. A RTOG phase II study (RTOG 9708) (336) was conducted to assess the feasibility, safety, toxicity, and patterns of recurrence and survival when chemotherapy was combined with adjuvant radiation for patients with high-risk EC. Pathologic requirements included grade 2 or 3 endometrial adenocarcinoma with either greater than 50% myometrial invasion, cervical stromal invasion, or pelvic-confined extra uterine disease. Radiation included 45 Gy in 25 fractions to the pelvis along with cisplatin (50 mg/m²) on days 1 and 28. Vaginal brachytherapy was performed after the external beam radiation. Four courses of cisplatin (50 mg/m²) and paclitaxel (175 mg/m²) were given at 4-week intervals following completion of radiotherapy. Forty-six patients were accrued to the study. Median follow-up was a median of 4.3 years. At 4 years, pelvic, regional, and distant recurrence rates were 2%, 2%, and 19%, respectively. OS and DFS rates at 4 years were 85% and 81%, respectively. Four-year rates for survival and DFS for Stage III patients were 77% and 72%, respectively. There were no recurrences for patients with Stage IC, IIA, or IIB. Local-regional control was reported to be excellent following combined modality treatment in all patients suggesting additive effects of chemotherapy and radiation. Distant metastases continued to occur in more advanced-stage patients.

Secord et al. (404) reported a multicenter evaluation of sequential multimodality therapy and clinical outcome for the treatment of advanced EC. A multicenter retrospective analysis of patients with surgical stages III and IV EC from 1993 to 2007 was conducted. Inclusion criteria included a comprehensive staging procedure including hysterectomy, bilateral salpingo-oophorectomy, +/- selective pelvic/aortic lymphadenectomy, and treatment with adjuvant chemotherapy and radiation. One hundred and nine patients with advanced-stage EC were identified who received postoperative adjuvant therapies; 41% ($n = 45$) received chemotherapy followed by radiation and then further chemotherapy (CRC), 17% ($n = 18$) radiation followed by chemotherapy (RC), and 42% ($n = 46$) chemotherapy followed by radiation (CR). There was no difference in the frequency of adverse effects due to either chemotherapy ($p = 0.35$) or radiotherapy ($p = 0.14$), dose modifications ($p = 0.055$), or delays ($p = 0.80$) between the various sequencing modalities. There was a significant difference between adjuvant treatment groups for both OS (log rank $p = 0.011$) and PFS (log rank $p = 0.025$), with those receiving CRC having a superior 3-year OS (88%) and PFS (69%) compared to RC (54% and 47%) or CR (57% and 52%). After adjusting for stage, age, grade, race, histology, and cytoreduction status, the OS HR for therapy was 5.74 (95% CI, 1.96–16.77) for RC and 2.60 (95% CI, 1.01–6.71) for CR, compared to CRC, $p = 0.003$. When the analysis was restricted to optimally cytoreduced patients, those who were treated with RC were at higher risk for disease progression (HR, 3.53; 95% CI, 1.29–9.71; $p = 0.024$) and death (HR, 7.24; 95% CI, 2.25–23.37; $p = 0.001$) than patients who received sequential CRC. The authors reported that sequential CRC was associated with improved survival in women with advanced-stage disease compared to other sequencing modalities with a similar adverse effect profile.

Metastatic/Recurrent Disease

The role of chemotherapy in the recurrent/metastatic setting remains palliative, and minimizing side effects is of equal importance when selecting a regimen. Previously discussed were the trials enrolling patients with metastatic disease, namely GOG 163, 177, and GOG 209 (389, 390, 393). As the role of chemotherapy in the postoperative setting has expanded, the choices in the recurrent/metastatic setting have shifted and, in some cases, narrowed. A variety of single cytotoxic agents that have been tested are presented in Table 22.19. Options and choices are dependent on prior treatment and, in some cases, disease-free interval. The most commonly used single agents today based on response rates of at least 20% include cisplatin, carboplatin, doxorubicin, epirubicin, ifosfamide, docetaxel, paclitaxel, and topotecan.

The response rate to **cisplatin** dosages of 50 to 60 mg/m² given every 3 weeks was similar in patients with prior (25%) (387, 405) and no prior chemotherapy (21%) (406–408). **Carboplatin** given in dosages of 300 to 400 mg/m² every 4 weeks has been associated with response rates of 29% (409–410), which is similar to cisplatin. **Doxorubicin** in dosages of 55 to 60 mg/m² has been associated with an overall response rate of 26% (411, 412), and **epirubicin** with a response rate of 26% (413). **Liposomal doxorubicin** was reported in a GOG study of 46 patients receiving 50 mg/m² every 4 weeks with an overall response rate of 9.5% (95% CI, 2.7%–26%) (414). It is important to note that 32 patients had received prior doxorubicin therapy. A second study evaluated its efficacy in 19 patients without prior chemotherapy treatment and resulted in a 21% response rate (415). Of the antimetabolites, **5-fluorouracil** was given in dosages of 15 mg/kg for 5 consecutive days and then every other day until dose-limiting toxicity occurred. It has displayed a 21% response rate in 34 patients, whereas **methotrexate** (416) and **mercaptopurine** (417) have been inactive. **Vincristine** given on

a weekly schedule was associated with a response rate of 18% in 33 untreated patients (418), but dose-limiting neurotoxicity was substantial. In a phase 2 trial of **paclitaxel** conducted by the GOG (396), 28 patients with recurrent or advanced EC received a dose of 250 mg/m² every 21 days. Patients who had received prior pelvic irradiation were treated at an initial dose of 200 mg/m². Complete responses were noted in four patients (14%) and partial responses in six (21%), for an overall response rate of 36%. A more contemporary GOG study evaluated paclitaxel at 200 mg/m² (175 mg/m² with prior radiotherapy) every 3 weeks in pretreated patients showing an overall response rate of 27.3% (95% CI, 15.0%–42.8%). The median duration of response was 4.2 months with an OS of 10.3 months (398). A similar study showed a response rate of 43% (95% CI, 6%–80%) in patients who had all previously been treated with platinum-based therapy (419). A multicenter trial recently reported showed a response

rate of 21% with PFS of 12 weeks and OS of 43 weeks in 35 patients receiving weekly **docetaxel** at 35 mg/m² (397). **Topotecan** was evaluated in a phase 2 trial of untreated advanced or recurrent EC administered initially at 1.5 mg/m² every day for 5 days every 3 weeks. The trial was suspended for toxicity, but reopened and completed at 1 mg/m² q day for 5 days (or 0.8 mg/m²/d for patients with prior radiotherapy). An overall response rate of 20% was seen with median duration of response of 8.0 months and OS of 6.5 months (420). A subsequent smaller study by Traina et al. using weekly topotecan dosing of 2.5 to 4.0 mg/m² on a 2 of 3 weeks schedule followed by 1 week off showed one partial response for 54 weeks with two patients having stable disease for 15 weeks each. Only two patients required dose reduction for toxicity using the weekly schedule (421).

Epothilones are a novel class of nontaxane microtubule-stabilizing agents that are currently approved for the management

Table 22.19 Single-Agent Trials

Agent (Reference)	n	Prior Treatment	No. of CR + PR	(%)	95% CI
<i>Alkylating Agents</i>					
Cyclophosphamide (425)	37	Some	4	11	3–25
Chlorambucil (425)	11	NS	0	0	0–28

Paclitaxel (396–398)	44	Yes	3 + 9	27.3	15–42.8
Docetaxel (397)	35	No	3 + 4	21	Nr
Ixabepilone (422)	50	Yes	1 + 5	12	Nr

95% CI, the 95% confidence interval for complete and partial response; CR, complete response; NS, not stated; Nr, not reported; PR, partial response.

of advanced breast cancer. Ixabepilone was recently reported to have an objective response rate of 12% with a PFS of 2.9 months and a stable disease and a stable disease rate for at least 8 weeks of 60% (422).

Regardless of the available choices, responses to each successive line of therapy are short lived. As such, focus has centered on the molecular basis of EC and potential targeted agents.

GENTETIC CHANGES IN ENDOMETRIAL CANCER AND TARGETED THERAPY

The molecular background of EC provides a platform that lends itself to targeted therapeutics in patients with advanced or recurrent disease. Biological agents targeting such molecular components are currently under development in numerous clinical trials. Focus has centered on specific histologic subtype- and/or biomarker-driven patient stratification. Evidence suggests that not only are type I and II endometrial tumors distinct entities with diversified genotypic and phenotypic profile (Table 22.20),

but also patients within each subtype may differ molecularly. Hence, efforts have focused on the application of personalized therapies by utilizing biomarkers able to discriminate patients' dominant profile (11, 436).

The **PI3K/AKT/mTOR pathway** represents a major signaling pathway downstream of several growth factor receptor kinases (e.g., epidermal growth factor receptor, platelet-derived growth factor receptor, fibroblast growth factor receptor, and insulin growth factor receptor) and is well known to have a pivotal role in cell survival and growth (437). The PI3K/AKT/PTEN pathway is the most commonly altered pathway in type I EC (438). Activation of PI3K leads to the phosphorylation of a secondary messenger to form PIP3 (phosphatidylinositol 3,4,5-triphosphate). This process is regulated by PTEN, which dephosphorylates PIP3 to PIP2. Activation of PI3K, resulting in PIP3, subsequently leads to AKT activation. AKT promotes cell growth, proliferation, reduces apoptosis, and increases angiogenesis. Two important regulators of the process include the mammalian target of rapamycin complexes mTORC 1 and 2.

The most common mechanisms of PI3K activation are loss of the phosphatase and tensin homolog (PTEN) tumor suppressor protein function, and activating mutations in catalytic PI3K

Table 22.20 Molecular Aberrations of Endometrial Cancer (EC) by Type

Molecular Aberration	Type I (Endometrioid) EC (%)	Type II (Nonendometrioid) EC (%)	Aberrant Pathway
PTEN loss	80–83	5	PI3K/AKT/mTOR pathway
PIK3CA			
Mutation	24–40	20	PI3K/AKT/mTOR pathway
Amplification	2–14	46	
PIK3R1 mutation	43	12	PI3K/AKT/mTOR pathway
AKT mutation	3	0	PI3K/AKT/mTOR pathway
KRAS mutation	10–30	0–10	Ras-Raf-Mek-Erk pathway
MSI	15–45	0–5	–
β -catenin (CTNNB1) mutation	14–50	0	Wnt/ β -catenin/LEF-1 pathway
E-cadherin loss	5–50	60–90	Wnt/ β -catenin/LEF-1 pathway
TP53 mutation	10–20	90	Tumor suppression
p16 loss	8	45	Cyclin D/CDK4-CDK6/RB
HER2			
Overexpression	3–10	32–43	Cell-surface receptor
Amplification	1	17–29	
FGFR-2 mutation	12–16	1	Cell-surface receptor
EGFR			
Overexpression	46	34	
Mutation	Unknown	0	
IGFIR overexpression	78	Unknown	Cell-surface receptor
Chromosomal Instability STK15, BUB1, CCNB2 LOH at multiple loci			–
EphA2 overexpression	48	Unknown	Transmembrane protein
EpCAM overexpression	Unknown	96	Transmembrane protein
HIF1a overexpression	25%	80%	Gene transcription nuclear protein
ARID1A mutation	29–40	18–26	Transcription-regulating process

subunit, p110 α , which is encoded by the PIK3CA gene. Cells that are deficient in PTEN may have a resulting activation of the PI3K pathway. The function of the tumor-suppressor gene *PTEN* includes inhibition of cell migration, spreading, and adhesion (439, 440). The *PTEN* gene is located on chromosome 10q23, and about 40% of endometrial carcinomas display loss of heterozygosity of chromosome 10q23, which suggests the involvement of *PTEN* in this disease (439, 441). *PTEN* mutations in 30% to 50% of endometrial carcinoma tumors make this the most frequent genetic alteration known in this disease (442, 443). Genes for the catalytic subunit of PI3K (PI3KCA) are frequently amplified (2–14% type I ECs, 46% type II) or mutated (30% type I–II) in EC, leading to constitutive activation (11).

mTOR is a conserved serine/threonine kinase that lies downstream of the phosphatidylinositol 3 kinase/PTEN/AKT pathway and is composed of two subunits, mTORC1 and mTORC2. Activated AKT phosphorylates mTOR directly or indirectly by phosphorylating TSC2 (Tuberous sclerosis complex 2), which in turn stimulates mTORC1. Subsequently, mTORC1 phosphorylates several transcription factors, namely S6K-1 (ribosomal S6 kinase-1) and 4E-BP1 eukaryote translation initiation factor 4E binding protein-1), thereby leading to the synthesis of proteins involved in proliferation and survival. The second subunit mTORC2 is much less defined, but may mediate activation of AKT in response to mTORC1 inhibitors (444).

The frequency of dysfunction and importance of the PI3K pathway in EC made this a predominate disease site targeted by inhibitors of this pathway (445). PI3K/AKT/mTOR pathway inhibitors undergoing active clinical investigation in EC are highlighted in Table 22.21 (446, 661–675). Of all the available inhibitors, the rapalogs temsirolimus (CCI-779®; Wyeth), ridaforolimus (deforolimus; AP23573®, MK-8669; Merck), and everolimus (RAD001®; Novartis), which specifically inhibit mTORC 1, are the compounds more extensively tested in EC clinical trials thus far (447).

Preliminary results of a phase II trial (448) of **temsirolimus** in recurrent or metastatic EC (chemotherapy naïve, with up to 1 prior line of hormonal therapy) demonstrated encouraging results with 5 confirmed partial responses (26%) out of 19 evaluable patients. Three of the partial responses were in patients with papillary serous tumors. Evaluation of a second cohort, women who must have had treatment with one prior regimen of cytotoxic chemotherapy, revealed an RR of 7% (2/27). Overall, temsirolimus activity was seen in all histologic subgroups and grades regardless of PTEN loss. The most frequent drug-related toxicities were fatigue, mucocutaneous irritation (acne-like maculopapular rashes, mucositis, stomatitis, and diarrhea), and pneumonitis. Grade 3 toxic effects were rare and included lymphopenia, neutropenia, thrombocytopenia, hyperglycemia, and hyperlipidemia. Temsirolimus has also been studied in combination with paclitaxel/carboplatin and has demonstrated good tolerability in a phase I trial (449), prompting the initiation of a phase II study. A recently reported GOG study combining temsirolimus with alternating hormones, megestrol acetate and tamoxifen, was closed secondary to high levels of venous thrombosis and insufficient additional activity to warrant further study (450). Temsirolimus is currently being explored in combination with other cytotoxic and biological agents, such as carboplatin/paclitaxel, pegylated liposomal doxorubicin, bevacizumab, AMG386, and AZD2171.

Two phase II clinical trials (451, 452) have demonstrated clinical response to intravenous **ridaforolimus** (12.5 mg/day for five days every other week) in chemotherapy-treated patients (451). A PR rate of 7.7% and an SD rate of 58% to oral ridaforolimus in chemotherapy-naïve patients (452) was also noted. In one study (453), patients with unresectable Stage III or IVA or metastatic disease were randomized to oral ridaforolimus (40 mg for 5 days/week) versus medroxyprogesterone (200 mg/d) or megestrol (60 mg/d). Interim analysis of the first 114 patients

Table 22.21 PI3K/AKT/mTOR Signaling Pathway Inhibitors

1. PI3K inhibitors—target p110 exclusively either as pan-p110 inhibitors and isoform-specific inhibitors (mostly ATP competitors)

Wortmannin (SL-2052; Tocris Bioscience)
LY294002 (SelleckBio)
XL147 (SAR245408; Exelixis)
NVP-BKM120 (Novartis)
GDC-0941 (Piramed/Genentech, Slough)
PX-866 (Oncothyreon)
PWT33597 (Pathway Therapeutics)
CAL-101 (Calistoga Pharmaceuticals)
ZSTK474 (SelleckBio)

2. Dual PI3K and mTOR inhibitors—target all catalytic isoforms of PI3K together with mTORC1 and mTORC2

NVP-BEZ235 (Novartis)
NVP-BGT226 (Novartis)
GDC-0980 (Genentech)
XL765 (SAR245409; Exelixis)
GSK 1059615 (GlaxoSmithKline)
SF1126 (Semafore Pharmaceuticals)
PF-04691502 (Pfizer)
PKI-587 or PF-05212384 (Pfizer)

3. AKT inhibitors—target serine/threonine kinase AKT (lipidbased phosphatidyl inositol analogues, ATP mimetics or allosteric inhibitors)

MK-2206 (Merck & Co)
GSK690693 (GlaxoSmithKline)
MKC-1 (EntreMed)
Perifosine (Keryx Biopharmaceuticals)
GSK2141795 (GlaxoSmithKline)
GSK2110183 (Octagon Research Solutions)
GDC-0068 (Genentech)
LY2780301 (Eli Lilly)
Inositol-1,3,4,5,6 pentakisphosphate (IP5)—(2-O-Bn-InsP5)
VQD-002 (API-2)

4. mTOR inhibitors—the rapalogs (synthetic rapamycin derivatives) target the FKBP12 binding protein, and directly the mTORC1 +/- mTORC2 complex

Rapamycin
Temsirolimus (CCI-779; Wyeth)
Everolimus (RAD001; Novartis)
Ridaforolimus (AP23573, formerly known as deforolimus—ARIAD; Merck & Co)
ATP-competitive mTORC1 and mTORC2 inhibitors
AZD8055 (Astra Zeneca)
OSI-027 (OSI Pharmaceuticals)

Ref. 518–522.

demonstrated a median PFS of 36 months for ridaforolimus and 1.9 months for progestin therapy (HR 0.53, $p = 0.008$) with grade 3/4 toxicities of hyperglycemia (19%) and anemia (9%). A trial investigating the combination of ridaforolimus with carboplatin/paclitaxel is underway. In a recent phase II trial (454), 35 heavily pre-treated patients with recurrent endometrioid EC received oral **everolimus** at a dose of 10mg daily. Results were encouraging, with 43% and 21% of patients achieving SD at 8 and 16 weeks, respectively. Most common drug-related toxicities included abdominal pain (28%), nausea and vomiting (21%), fatigue, anemia, and lymphopenia. An attempt to correlate response to the molecular status of the primary tumor failed to reveal any significant predictive marker, although a trend for K-RAS mutation correlation with therapy resistance was noticed (455). A study of everolimus and letrozole in pre-treated recurrent EC achieved a response rate of 21%, including one CR and three PRs. Furthermore, four patients had SD and seven still remain on treatment (456).

Microsatellite instability (MSI) is found in 20%–45% of type I tumors (0–5% type II tumors), and is caused by inactivation of DNA repair genes such as MLH1, MSH2, MSH6, and PMS2 (457, 458). Tumors with MSI have instability (insertions and deletions) in the simple repeated sequences found in coding and noncoding elements of many genes. Resulting frameshift mutations may inactivate some genes including PTEN. MSI was first described in HNPCC. One of the most common extracolonic tumors associated with this disease is EC, and MSI has been demonstrated in both hereditary and sporadic tumors (459). MSI in EC has been reported to be between 9% and 43% (460–462). In 71% to 92% of sporadic endometrial carcinoma, MSI has been found to be associated with hypermethylation of the *bMLH1* promoter region, whereas it seems to be less common in the promoter region of *bMSH2* (463). It is likely that methylation of the promoter region is an important mechanism of *bMLH1* gene inactivation in endometrial carcinoma (449) and a precursor to MSI. Too few studies have been done to reach any conclusion regarding the importance of MSI as a prognostic factor in EC, although defects in MMR systems may alter responsiveness to chemotherapy or radiation (465). Deletions or mutations of the *PTEN* gene, and MSI due to hypermethylation of the promoter for the mismatch repair gene *bMLH1*, are both relatively common and early events in the development of a significant proportion of type I endometrioid adenocarcinomas. In contrast, these molecular alterations do not appear to be critical in the pathogenesis of serous or clear-cell carcinoma. However, mutations in the p53 gene are found with high frequency not only in invasive serous carcinoma but also in EIC (247, 466), the noninvasive precursor of serous carcinoma, suggesting that a different pathway is followed in the development of the second type of endometrial adenocarcinoma.

TP53 is a tumor-suppressor gene, the product of which is a protein involved in the regulation of the cell cycle at the G1 checkpoint, permitting replication of cells that have acquired various mutations. Mutations of the p53 gene often result in a protein with a longer half-life, which accumulates in the cell. Up-regulation of wild-type (i.e., nonmutated) p53 may occur after DNA damage and also results in overexpression that is detectable by immunohistochemistry. This appears to be an early event in the development of serous carcinoma, but it is a late event in endometrioid carcinomas for which it serves as an indicator of poor prognosis. In addition to the very frequent overexpression of p53 protein in serous carcinoma (467), it has also been related to a higher FIGO stage, clear-cell histology, higher histologic grade, and increased depth of myometrial invasion (467, 468). Lundgren et al. (469) studied p53 in relation to clinicopathologic variables in 376 consecutive patients with EC stages I–IV. p53 overexpression was found to be a strong significant factor with regard to relapse-free survival in univariate analysis, but it failed to retain its significance when submitted to multivariate analysis.

In contrast, p53 mutations are not often found in type I, low-grade endometrioid tumors (470). This suggests that different subgroups of ECs have different genetic pathways. Much more work is needed to understand the genetic mechanics at play and to translate this into use within the clinical and therapeutic field.

EGFR/Her/ErbB family is composed of four structurally similar tyrosine kinase – functioning receptors: EGFR (epidermal growth factor receptor, HER1), ErbB2 (HER2/neu), ErbB3 (HER3) and ErbB4 (HER4). Their activation triggers a cascade of events ultimately leading to cell proliferation and survival (471). This molecular family has garnered a great deal of interest given that it activates important downstream pathways including VEGF, PI3K/AKT and Ras/Raf/MEK (472). EGFR family-directed therapies include both small molecule tyrosine kinase inhibitors (e.g. erlotinib, gefitinib and lapatinib) and anti-EGFR monoclonal antibodies (e.g. cetuximab and trastuzumab). Yet, despite EGFR overexpression in both EC subtypes (473), and favorable preclinical studies using EGF receptor antagonists (474), clinical trials in unselected EC population have shown little promise.

HER2/neu is a proto-oncogene, the product of which is a transmembrane growth factor receptor, p185erb-2, which shares some homology with the epidermal growth factor receptor. It is normally expressed at low levels in the cycling endometrium. HER2/neu is frequently over expressed or amplified in 10–30% of type I and 40–80% of type II ECs (475), and has been associated with advanced stage (476), decreased differentiation, aggressive cell types particularly including the clear-cell type (479), and deep myometrial invasion. The significance of HER2/neu amplification or over expression as a predictor of survival is somewhat unclear, with no apparent association of overexpression to outcome being identified in several studies (467, 478, 480), but a statistically significant relationship in most others (477–481, 482) even after adjusting for other known risk factors (477). In addition to its potential utility as an indicator of poor prognosis, systemic therapy using antibodies directed against the HER2/neu protein has been investigated for patients with tumors that express the protein at high levels. **Trastuzumab** (Herceptin®, Genentech) monotherapy failed to demonstrate significant activity in the recent GOG 181-B study (483). No responses were achieved, although 12 of 34 women experienced stabilization. Given the higher rates of HER2 overexpression seen in type II tumors, assessment of trastuzumab combined with carboplatin/paclitaxel in serous papillary tumors is underway.

Erlotinib (Tarceva®, GenenTech) (150 mg/day orally) was evaluated in 32 assessable women with chemotherapy-naïve, recurrent or metastatic EC (484). One prior line of hormonal therapy was permitted. The overall response rate was 13% (12.5% with confirmed PR lasting 2 to 36 months and 47% with SD with a median duration of 3.7 months). The treatment was very well tolerated with elevated transaminases being the only grade 4 toxicity. EGFR expression was noted to be positive in 19 patients and negative in 9 patients. Three of the 19 patients with overexpression (16%) had a PR. There were no EGFR mutations identified, and there was no correlation with gene amplification and response. Given the poor overall response rate of 4% and SD of 27% of **gefitinib** (Iressa®, AstraZeneca) (500 mg/day) in the GOG 229-C trial (485) no further studies have been undertaken. EGFR mutations, as well as expression of EGFR, phosphor-EGFR, phosphor-ERK were examined in tumors but did not correlate with clinical response. A phase II study of **cetuximab** (Erbixux®, Bristol-Myers Squibb) in progressive or recurrent EC was recently completed and its results are eagerly waited. The novel dual EGFR and HER2 tyrosine kinase inhibitors, **lapatinib** (Tykerb®, GSK), was evaluated in the phase II GOG 229-D study. Although no data have been published by this trial, second stage accrual was not

opened, likely indicating low clinical activity. Clinical trials focusing on preselected patients are ongoing (e.g., **BIBW 2992** [afatinib], an oral ErbB family blocker that covalently binds and irreversibly blocks all kinase-competent ErbB family members, and **ARRY 380**, an orally active, reversible and selective ErbB-2/HER2 inhibitor) while much effort is currently focused on effective combinations of EGFR with other agents that can overcome the molecular “escape” pathways for EGF receptor antagonists.

The **RAS/RAF/MEK pathway** is involved in several crucial cellular functions including angiogenesis, cell cycle regulation, proliferation and survival. The activation of RAS proto-oncogenes through either point mutations or gene amplification has been identified in various malignant tumors. Mutations in the *K-ras* oncogene have been reported in endometrioid cancer and also in endometrial hyperplasia, suggesting that *K-ras* activation may be an early event in the development of endometrioid malignancy. In most studies, the presence of *K-ras* mutations has not been related to stage, grade, depth of invasion, or survival (486, 487). *K-ras* mutations may activate the PI3K pathway independent of traditional signaling (488, 489). This pathway is under the direct control of upstream cell-surface growth receptors that are often affected in EC. Beside the relatively high prevalence of *K-ras* mutations identified in EC (Table 22.20), recent data has also illustrated an interesting negative feedback loop involving pS6K. Ramjaun and colleagues recently reported that this pathway is activated in the presence of AKT blockade (490). MEK inhibitors and RAF kinase small molecule inhibitors are currently being investigated. The GOG has explored a single-agent phase II trial of the oral MEK inhibitor **selumetinib** (AZD6244) in patients pre-treated with recurrent or persistent EC. Although adequate response rates were achieved, frequent and severe side effects have halted this trial. Clinical trials under development have now focused on the simultaneous blockade of components of both Ras/Raf/MEK and PI3K/AKT/mTOR pathways (490).

Angiogenesis mediates the growth of several solid tumors including that of endometrial cancer. Overexpression of VEGF has been associated with poor prognostic factors in EC such as deep myometrial invasion and lymph node metastasis (491, 492). VEGF expression seems highly variable depending on histologic subtype and disease stage, with early-stage well-differentiated lesions expressing the highest levels (493). To date, treatment of recurrent EC with antiangiogenic agents has revealed mixed results.

The most significant developments in this class of agents have centered on suppressing the VEGFR ligand. **Bevacizumab** (Avastin®, Roche) (15 mg IV every 3 weeks) was investigated in GOG-229E, a study in patients with recurrent or persistent measurable EC after receiving one or two prior cytotoxic regimens (494). Of fifty-two evaluable patients, 13.5% had objective response (one CR and six PRs) while 40.4% of patients survived progression-free for at least 6 months. Median PFS and OS were 4.2 and 10.5 months, respectively. Although no GI perforations or fistulas occurred, two episodes of grades 3/4 hemorrhage and thromboembolism were reported. Bevacizumab is currently being evaluated in a three-arm randomized phase II GOG study (86P) with patients randomly assigned to carboplatin/paclitaxel/bevacizumab, carboplatin/paclitaxel/temsirolimus, and carboplatin/ixabepilone/bevacizumab. Other trials under evaluation include first-line intensity-modulated irradiation/cisplatin/bevacizumab followed by carboplatin/paclitaxel.

Tyrosine kinase receptor inhibitors are among the various targeted therapeutics under investigation. These agents target several receptors allowing for the pharmacological disruption of several independent pathways. **Sunitinib malate** (Sutent®, Pfizer) is an oral small-molecule, multitargeted tyrosine kinase inhibitor that targets several receptor tyrosine kinases. In one study (495), 20 evaluable patients with recurrent or metastatic EC, previously treated with at most one chemotherapy regimen,

received 50 mg sunitinib daily for 4 consecutive weeks followed by 2 weeks off. Three patients (15%) achieved PR and five (25%) achieved stabilization of the disease, four of which were for more than 6 months. Median time to progression and OS were 2.5 and 19.0 months respectively.

Unfortunately, the antiangiogenic and antiproliferative properties of **sorafenib** (Nexavar®, Bayer) (495) and **thalidomide** (Thalomid®, Celgene) (496) did not lead to significant objective responses in the corresponding phase II clinical trials and were deemed not clinically interesting enough to justify further study. New antiangiogenic agents undergoing phase II clinical trials in pretreated EC include the angiokinase inhibitors **brivanib**, **cediranib**, **E7080**, **BIBF1120**, and the VEGF-Trap **aflicercept** (GOG 229-F).

Metformin is a biguanide drug that is widely used for the treatment of type II diabetes. Several studies have suggested that this agent can reduce cancer incidence among hyperglycemic patients. Since the first case report describing metformin-induced regression of AEH in one patient nonrespondent to progesterone therapy, a continuously growing body of evidence has brought metformin to the foreground of therapies against EC. Not only does this antidiabetic agent improve the negatively associated EC metabolic profile (insulin resistance, obesity, estrogen excess) (498, 499), but it also exhibits activity against EC cells through antiproliferative, proapoptotic, antiangiogenic, and antimetastatic properties (500–502). Metformin is commonly thought of as an insulin sensitizer resulting in an improvement in insulin resistance, followed by a reduction in circulating insulin levels. Metformin inhibits complex I activity in the mitochondria leading to the activation of its downstream target, AMPK, which regulates multiple signaling pathways controlling cellular proliferation, including inhibition of the mTOR pathway (503). Given the interrelationship between these two pathways, metformin is thought to behave as a novel mTOR inhibitor and has been shown to dramatically decrease proliferation in a number of different human cancer cell lines *in vitro* (504). Hanna et al. demonstrated a synergistic relationship between paclitaxel and metformin against human EC cell lines (505). A prospective trial is currently being conducted evaluating metformin's effect in patients with EC without concurrent diabetes.

The Poly (adenosine diphosphate ribose) polymerase (PARP). is a family of nuclear, multifunctional enzymes that mediates the recruitment of the DNA repair machinery through the base-excision repair (BER) pathway (506). The anti-neoplastic effect of PARP inhibitors stems from their ability to enhance the genomic instability of tumor cells by simultaneously targeting DNA repair pathways and exploiting their intrinsic deficiencies in the homologous recombination (HR) pathway through the phenomenon of synthetic lethality (506). PTEN loss is considered a component of BRCA-ness phenotype. It impedes repair of DNA double-strand breaks via homologous recombination, thereby creating cellular susceptibility to PARP inhibition (507). Preclinical data have shown a correlation between *in vitro* sensitivity to PARP inhibition and mutated PTEN status in EC cell lines (508), providing a strong rationale for testing PARP inhibitors in EC, especially type I, which harbors PTEN functional loss in 80% of cases. There is a variety of PARP inhibitors in clinical development, including olaparib, veliparib, and iniparib. A phase I study evaluating olaparib observed a dramatic clinical response in one BRCA mutation negative patient with metastatic EC. After 6 weeks of treatment, complete resolution of symptoms as well as radiologic response of visceral metastases were noted (509). Iniparib (BSI-201) has been studied in the treatment of recurrent carcinosarcoma of the uterus in combination with carboplatin and paclitaxel. The results of this study have not been formally reported. Further clinical evaluation of the potential utility of PARP inhibitors in EC is warranted.

MANAGEMENT OF PATIENTS WITH SEROUS AND CLEAR-CELL HISTOLOGIES

Serous cancer and, to a lesser extent, clear-cell ECs tend to spread in a fashion similar to ovarian cancer with a high propensity for upper abdominal relapse. Therefore, whole-abdomen radiation has been extensively studied historically in this group of patients (335). Given the mixed results with whole-abdomen radiotherapy, the recognized patterns of disease spread and failure, and the findings of GOG 122 (289) supporting an increased role for chemotherapy, chemotherapy has increasingly been used to treat these high-risk histologies. Based on the response rates of paclitaxel and carboplatin in other tumors of serous histology, trials investigating paclitaxel and carboplatin in UPSCs have reported response rates of 60% to 70% (510, 511). No randomized, prospective trials evaluating multi-modality therapy specifically for early- or late-stage uterine serous carcinomas have been reported. A single-institution phase 2 trial for advanced-stage uterine papillary serous histology administered paclitaxel and platinum-based chemotherapy for three cycles followed by volume-directed radiation therapy. Patients then received an additional three cycles of chemotherapy. The most common toxicity was hematologic and occurred during chemotherapy following radiation therapy. The PFS for the nine women treated is 46.4 months (512). A similar study administered four cycles of platinum with paclitaxel or epirubicin followed by whole pelvic and vaginal brachytherapy. The 5-year OS for this group was 58.9% (513).

With regard to Stage I disease, the available data for designing a treatment plan are retrospective. A study of 74 Stage I patients with UPSC between 1987 and 2004 who underwent complete staging at Yale University was reported (514). Patients were divided into those who had no residual cancer in the hysterectomy specimen versus those who did. Stage IA patients who had residual in the hysterectomy specimen and who were treated with platinum-based chemotherapy had no recurrences ($n = 7$) versus 6 of 14 (43%) who did not receive treatment. Of 15 patients with Stage IB disease, there were no recurrences in the treated group, but 10 of 13 nontreated patients (77%) recurred. Platinum-based chemotherapy was associated with improved progression-free ($p < 0.01$) and OS ($p < 0.05$). Furthermore, no patient who received radiation to the vaginal cuff recurred at the cuff versus 6 of 31 (19%) of those who did not receive vaginal cuff irradiation (514). Recognizing the limits of retrospective studies, these data support the potential benefit of a regimen of platinum-based chemotherapy with cuff irradiation in patients with UPSC. Randomized, prospective data are needed to accurately define the best approach in these patients.

In 2009, the SGO produced a review of the management of women with serous EC (515). It was noted that as extra-uterine spread was common, even in the setting of minimally invasive/noninvasive disease, surgical staging should be routinely performed. In addition, platinum-based chemotherapy should be considered in both early-stage and advanced-stage patients. The role of radiation in these patients by itself or in combination

with chemotherapy remains uncertain, and is being addressed by the GOG 249 and GOG 258 protocols. In addition, the SGO also sponsored a review of clear-cell carcinoma of the uterus, which supported routine staging, and consideration of post-operative chemotherapy (516). The rarity of these tumor types has made histology-based clinical trials difficult to perform. It is hoped that as a better understanding of the molecular pathways evolves in EC, treatment based on histology may become more common. At the present time, using standard chemotherapy regimens, there are no data to support different therapies based on histology alone (16).

FUTURE DIRECTIONS

In 2001, the National Cancer Institute convened an expert panel to develop a national 5-year plan for research priorities in gynecologic cancers. The resulting report, Priorities of the Gynecologic Cancer Progress Review Group (PRG), specified that understanding tumor biology was the central key toward controlling gynecologic cancers. Now, nearly a decade later, some hope for a better understanding of EC at a genetic and molecular level is being realized. The GOG 210 study, a prospective surgical pathologic study that created an annotated tissue repository from over 6000 patients with more than 36,000 specimens serves as a resource for discovery and validation of predictive and prognostic biomarkers. In addition, the Genome Atlas Project has nearly completed an analysis of 500 ECs (endometrioid and serous types) with array-based analyses and second-generation sequencing, which will provide information on genome copy number, gene expression profiles, methylation status, and whole exome sequencing, and will completely sequence 10% of all cases. It is expected that the knowledge from these datasets will drive clinical research and patient care for the next decade. Increasingly, we can expect that therapies offered to our patients will be based on a more complete understanding of pathways, and that therapies may be matched to address specific genetic changes.

Summary

EC is the most common gynecologic malignancy, and an understanding of presentation, surgical management, and treatment options is required for gynecologic oncologists. Surgical therapy is a mainstay of EC, with lymphadenectomy and laparoscopy increasingly integrated. A thorough knowledge of the relationships between uterine factors and extrauterine disease spread is essential. Surgical staging defines extent of disease and largely defines risk of recurrence. Pelvic radiation is associated with better local control, but no improvement in survival for patients with Stage I–II EC is seen in randomized trials. Chemotherapy is increasingly integrated into up-front management of advanced-stage EC and may have a role in early-stage disease. Combination therapy with radiation and chemotherapy is under evaluation. Targeted agents hold promise; however, a better understanding of molecular and genetic changes is required to improve efficacy.

MARIO M. LEITAO JR ■ CARMEN TORNOS

■ AARON H. WOLFSON ■ ROISIN O'CEARBHAILL

Mesenchymal tumors of the uterine corpus are rare, accounting for approximately 7% to 8% of all uterine cancers (1). The outcomes of many of these tumors seem to be less favorable than many of the more common uterine carcinomas. However, outcomes do vary significantly based on the specific histology. This is a group of tumors felt to arise from the mesenchymatous portion of the uterine corpus and often considered as uterine “sarcomas.” The World Health Organization (WHO) classification of mesenchymal uterine corpus tumors is summarized in Table 23.1 (2). Uterine carcinosarcomas are probably not best classified as a uterine sarcoma or mesenchymal tumor any longer, but rather should be classified as a metaplastic carcinoma of the uterus (3). However, uterine carcinosarcomas will be described in this chapter. A key concept of uterine sarcomas is that they are truly heterogeneous tumors with vastly different clinical presentations, responses to therapy, and outcomes. Much of the available literature, until more recently, is extremely limited by lumping all uterine sarcomas into one cohort.

EPIDEMIOLOGY AND RISK FACTORS

Histologic Distribution

Histopathologic criteria for uterine sarcomas have greatly evolved over the last few years and, therefore, histologic distribution may have shifted. Many series do not include or specify sarcoma subtypes and many are very small in number. Combining series with at least 100 cases including carcinosarcomas, the most common uterine sarcomas are leiomyosarcoma and carcinosarcoma (4–9) (Fig. 23.1A). Leiomyosarcomas account for over two-thirds of uterine sarcomas when excluding carcinosarcomas (4–10) (Fig. 23.1B). Endometrial stromal sarcomas (ESSs) account for approximately 25% of true uterine sarcomas with all of the other subtypes being exceedingly rare and accounting for <10% as a whole (4–10) (Fig. 23.1B). ESSs are by definition now considered all “low-grade.” Undifferentiated uterine sarcoma is now the preferred terminology for what was previously called “high-grade” ESSs. Therefore, endometrial stromal sarcoma information in this chapter primarily refers to these “low-grade” lesions. Abeler and colleagues have the most recent and largest series of uterine sarcomas ($n = 419$) from the Norwegian Cancer Registry, in which histologic subtype distribution was described (10). This series excluded carcinosarcomas altogether. Of these 419 sarcomas, 62% were leiomyosarcomas, 20% were ESSs, and 18% were various other subtypes that included undifferentiated sarcomas (6%), adenosarcomas (5.5%), sarcoma, not otherwise specified (NOS) (4.5%), rhabdomyosarcoma (<1%), giant-cell sarcoma (<1%), and perivascular epithelioid cell tumors (PEComa; <1%) (10).

Age Distribution

Patients with carcinosarcomas and adenosarcomas tend to be older at the time of diagnosis compared to those with leiomyosarcomas and ESSs. The mean/median ages reported among published series range from 42 to 51 years for ESSs (4,5,9,10–15), 48 to 57 years for leiomyosarcomas (4,5,9,10,16–18), 57 to 67 years for carcinosarcomas (4,5,9,19,20), 58 to 66 years for adenosarcomas (10,21), and 46 years for undifferentiated sarcomas (11). Subsequently, many patients with carcinosarcomas are postmenopausal at the time of diagnosis, whereas patients with leiomyosarcoma, endometrial stromal sarcoma, or undifferentiated sarcomas may be pre- or perimenopausal at the time of diagnosis. Additionally, the mean age for patients diagnosed with smooth muscle tumors of uncertain malignant potential (STUMP) is 43 years, and many patients are also likely to be premenopausal (22). This would have potential implications in terms of fertility in these patients. The other subtypes are so rare that it is difficult to discern a particular pattern of age distribution.

Racial Distribution

Zelmanowicz et al. (23) noted that women with carcinosarcomas are more likely to be of African American descent (among 453 patients and controls, 28% vs. 4%, $p = 0.001$) than those with endometrial adenocarcinomas. In the reviews of Mortel et al. and Norris et al. (24,25), 33% and 24% of patients with carcinosarcomas were non-White, respectively. Brooks et al. (26) reported that the age-adjusted incidence of uterine sarcomas in African American women was twice that of controls. The age-adjusted incidences of leiomyosarcomas for Black and White women, respectively, were 1.5 and 0.9 per 100,000. Those for carcinosarcomas in Black and White women, respectively, were 4.3 and 1.7 per 100,000.

Risk Factors

Prior Radiation Exposure

Prior exposure to pelvic radiotherapy is thought to increase the risk of developing a subsequent uterine sarcoma, primarily carcinosarcoma and undifferentiated sarcoma. Prior pelvic radiotherapy is not thought to increase the risk for uterine leiomyosarcoma or STUMP. In a large series from the Mayo Clinic, only 1 (0.6%) of 208 leiomyosarcoma cases had been exposed to prior pelvic radiotherapy (27). None of the 41 STUMP cases described by MD Anderson Cancer Center had a history of prior

pelvic radiotherapy (22). Christopherson et al. (28) described two cases among 33 patients with uterine leiomyosarcoma who had a history of radiotherapy.

In the series of carcinosarcomas reported by Norris et al. in 1966 (25), 9 of 31 patients (29%) had received pelvic radiotherapy from 7 to 26 years prior to diagnosis. Among 1,208 uterine malignancies in a report by Meredith et al. in 1986 (29), only 30 (2.4%) occurred in patients exposed to prior pelvic radiotherapy. Only 8 of these 30 patients had been irradiated for a gynecologic malignancy; others received pelvic radiation therapy for a benign diagnosis as this was done decades ago. Of irradiated patients, 5 (17%) developed carcinosarcomas, for a crude association of 11%. The risk of endometrial adenocarcinoma arising after radiation was much less at 2%. It has been suggested that postirradiation carcinosarcomas occur at a younger average age than those arising *de novo* (30). Latency to diagnosis of malignancy is generally shorter in older patients, however (29). Pothuri et al. compared the clinicopathologic characteristics of 23 cases of uterine cancers that occurred in patients with a prior history of cervical cancer treated with pelvic radiotherapy to 527 cases of uterine cancers that developed in patients without a history of pelvic radiotherapy (31). Carcinosarcomas and undifferentiated sarcomas accounted for 9 (39%) of the 23 radiation-associated malignancies compared to only 33 (8%) of the sporadic cases (31). It also seems that these radiation-associated malignancies tend to have a worse outcome, possibly due to lack of early symptomatology. The rarity of the other uterine sarcoma subtypes precludes the ability to make any definitive statements regarding this issue.

Hormone Exposure

There have been some suggestions that exposure to hormonal medications, including tamoxifen, may also increase the risk of uterine sarcomas. The association of estradiol-progestin therapy was recently assessed using data from the Finnish Cancer Registry, which captures nearly 100% of all cancers in Finland as well as the Reimbursement Registry of the Social Insurance Institution (32). Uterine sarcomas occurred in 76 out of the 243,857 women who were identified as having had used estradiol-progestin therapy for more than 6 months. Carcinosarcomas were not included in this analysis. The ever use of estradiol-progestin therapy was associated with a 60% elevation in the risk for

any uterine sarcoma (SIR, 1.6; 95% confidence interval [CI], 1.2–1.9). This association was mostly for leiomyosarcoma (standardized incidence ratio [SIR], 1.8; 95% CI, 1.3–2.4) and not statistically for endometrial stromal sarcoma (SIR, 1.4; 95% CI, 0.9–2.1). Also, this elevated risk was only noted in women who had used estradiol-progestin therapy for 5 years or more. Despite a possible increased relative risk, the overall absolute risk of uterine sarcomas is still exceedingly low, and these data should not dissuade the use of hormones in the appropriate case.

Tamoxifen Use

Tamoxifen use among breast cancer patients may also increase the risk of uterine malignancies, including possibly sarcomas. Lavie and colleagues, using data from 1,507 cases of women with breast cancer in the National Israeli Cancer Registry diagnosed from 1987 to 1988, noted that uterine cancers developed in 17/886 (1.9%) women treated with tamoxifen compared to only 4/621 (0.6%) of those who did not receive tamoxifen (odds ratio [OR], 3.1; 95% CI, 1–9.1) (33). The risk of uterine cancer was associated with increased duration of tamoxifen use (OR, 6.6; 95% CI, 2.0–21.1), whereas use of tamoxifen for 2 years or less was not associated with an increased risk of uterine cancer (OR, 2.1; 95% CI, 0.4–11.6). Uterine sarcomas developed in only 4 cases of the entire cohort. These included 2 carcinosarcomas and 2 rhabdomyosarcomas. All 4 occurred in patients who received tamoxifen, suggesting a possible association of tamoxifen use and uterine sarcoma risk. Hoogendoorn and colleagues reported that among patients diagnosed with uterine cancer, carcinosarcomas accounted for a much larger proportion of cases in those who had received prior tamoxifen therapy compared to those who had not (15% vs. 4%, respectively) (34).

Hereditary Predisposition

Hereditary predisposition to certain uterine sarcomas has also been suggested but still remains to be clearly elucidated. Among 164 Hereditary nonpolyposis colorectal cancer (HNPCC) families with disease-predisposing mutations, sarcomas of various sites represented 1% ($n = 14$) of the 1,570 malignant diagnoses using cases from the Danish HNPCC-register (35). Three of these 14 sarcomas were uterine: one was a carcinosarcoma in a 44-year-old with loss of MSH2 and MSH6 expression in the sarcoma, other was also a carcinosarcoma in a 55-year-old with loss of MSH6 expression, and the still other was a leiomyosarcoma in a 44-year-old with loss of MSH2 and MSH6 expression. Uterine leiomyosarcoma has also been recently suggested to be increased in women with hereditary retinoblastoma (36). The overall risk of uterine sarcoma is still low in these hereditary syndromes but of interest. Prophylactic hysterectomy is strongly recommended in women from HNPCC kindred once childbearing is complete due to the high risk of endometrial carcinoma, but no such recommendation exists for women with hereditary retinoblastoma since this is a recently described potential risk.

CLINICAL PRESENTATION AND DIAGNOSIS

Presenting Symptoms and Signs

The most common presenting symptom of uterine sarcomas is abnormal vaginal bleeding (4,11,13,21,26,36) (Table 23.2). Patients with leiomyosarcomas will also often note an abdominopelvic mass or one that is palpable on physical examination (4,26). A large number of leiomyosarcomas and ESSs are incidentally diagnosed after surgery for presumed uterine fibroids. The presence of endometrial stromal sarcoma was an incidental

Table 23.2 Common Presenting Symptoms in Patients with Uterine Sarcomas (% of Cases Describing that Symptom)

Symptom	ESS (4,11,13)	CS (4)	LMS (4,26)	AS (21,36)
Asymptomatic	14%	7%	11%	12%
Abnormal vaginal bleeding	68%	68%	53%	61%
Abdominopelvic mass	14%	16%	48%	—
Abdominopelvic pain	18%	9%	23%	20%
Uterine enlargement	64%	—	—	—
Uterine cavity lesion	21%	—	—	—
Vaginal discharge	4%	—	—	—
Abdominal distention	—	—	—	2%

ESS, endometrial stromal sarcoma; CS, carcinosarcoma; LMS, leiomyosarcoma; AS, adenosarcoma.

finding in 42% of cases reported by Memorial Sloan-Kettering Cancer Center (15). Therefore, it is quite likely that the vast majority of cases ultimately diagnosed with leiomyosarcoma or endometrial stromal sarcoma would have had some abnormal enlargement of the uterus discovered after presenting with abnormal vaginal bleeding. Vaginal bleeding in a postmenopausal female should be evaluated appropriately with endometrial sampling and possibly an intravaginal ultrasound. An enlarging pelvic mass in a postmenopausal female should also cause some concern for a malignant process. These symptoms and signs in premenopausal patients are a challenge and the diagnosis of malignancy is missed or often delayed since multiple benign conditions are more likely to be the cause of these symptoms. Carcinosarcoma often presents with vaginal bleeding in a postmenopausal female and often can be diagnosed with endometrial assessments, as it is a lesion that arises in the endometrium (unlike the true uterine sarcoma that often does not have an endometrial component or involve the endometrium).

There are no reliable serum tumor markers for uterine sarcoma. Serum CA-125 is elevated in 17% to 33% of leiomyosarcoma, ESSs, and carcinosarcomas (4). It should not be routinely used in the evaluation and diagnosis of these tumors. Preoperative endometrial assessments with either office pipelle or dilation and curettage (D&C) under anesthesia are limited in the evaluation and correct diagnosis of uterine sarcomas. However, endometrial assessments should be performed in women who present with abnormal vaginal bleeding, and uterine sarcoma may be discovered during this assessment. Bansal et al. reported that an invasive tumor was diagnosed in 86% of uterine sarcoma cases that had undergone a preoperative endometrial sampling (37). The correct histology for uterine sarcoma was only noted in 64% of the cases ultimately diagnosed with uterine sarcoma (37). However, the majority of the sarcomas in the series by Bansal and colleagues were carcinosarcomas on final pathology (32 [70%] of 46 sarcomas), with only 4 leiomyosarcomas, 2 endometrial sarcomas, and 8 other sarcomas diagnosed on final pathology (37).

Preoperative Imaging

Preoperative imaging is limited in differentiating benign from malignant uterine lesions, especially in the absence of obvious

extrauterine disease, but it is often available as part of the initial evaluation of these patients. Carcinosarcomas are often diagnosed using endometrial sampling; therefore, preoperative imaging is not important in the diagnosis for carcinosarcomas, but may be valuable in assessing for the presence of extrauterine disease. Small, single-institution, retrospective series have suggested that pelvic MRI may be of value in identifying uterine sarcomas and distinguishing them from benign uterine lesions. Namimto et al. reported a 100% sensitivity and specificity using diffusion-weighted imaging (DWI) and T2-weighted MR imaging in distinguishing between uterine sarcoma and benign lesions compared to DWI alone (38). This seems quite promising but not likely to be possible in clinical practice and not likely to be reproducible reliably. For example, Cornfeld and colleagues reported very poor accuracy for various objective MR imaging criteria in distinguishing leiomyomas with atypical imaging features from malignant uterine mesenchymal tumors (39). Using these various specific MR imaging criteria, the sensitivities for uterine sarcoma ranged from only 17% to 56% but the specificity was 80% to 100% (39).

Serum LDH and MR Imaging

Serum lactate dehydrogenase (LDH) may be an interesting additive to imaging in the evaluation of uterine lesions concerning for leiomyosarcomas (Table 23.3). Goto and colleagues reported an accuracy rate of 99.3% in predicting uterine leiomyosarcoma when combining serum LDH and dynamic MRI in a prospective trial (40). The positive predictive value was 91% using the combined assessment compared to 39% for LDH alone and 71% for MRI (dynamic or not). These results are impressive and would require further validation, but it is simple enough to obtain a serum LDH in patients with concerning lesions of the uterus. Another important point is that the series by Goto and colleagues, as well as other series, note a high specificity and nearly 100% negative predictive value for MRI with or without LDH. This can be useful in women who do not wish to undergo surgery and, especially, in women who are extremely desirous of fertility. It may also help when deciding upon the surgical approach in patients with presumed benign leiomyomas as well as much “concerning” lesions.

Table 23.3 Test Characteristics Using Dynamic MRI and Serum Lactate Dehydrogenase (LDH) in Predicting Uterine Leiomyosarcomas from Degenerating Leiomyomas

Test	Sensitivity	Specificity	Accuracy	PPV	NPV
Total serum LDH	100%	87.7%	86.6%	38.5%	100%
MRI	100%	96.9%	97.1%	71.4%	100%
Dynamic MRI	100%	87.5%	90.5%	71.4%	100%
LDH & dynamic MRI	100%	99.2%	99.3%	90.9%	100%

PPV, positive predictive value; NPV, negative predictive value.

Source: Adapted from Goto A, Takeuchi S, Sugimura K, et al. Usefulness of Gd-DTPA contrast-enhanced dynamic MRI and serum determination of LDH and its isozymes in the differential diagnosis of leiomyosarcoma from degenerated leiomyoma of the uterus. *Int J Gynecol Cancer*. 2002;12:354–361, with permission.

Uterine Morcellation

Laparoscopy has become a standard and preferred approach in the management of women with benign and malignant gynecologic conditions. Morcellation of the uterus, either for removal of the specimen during minimally invasive procedures, myomectomy for fertility preservation, or supracervical hysterectomy, is commonplace. Morcellation of the uterus is often not done in patients with carcinosarcomas since they are often older and the diagnosis of malignancy is known preoperatively. However, it is not unusual that a leiomyosarcoma or endometrial stromal sarcoma is incidentally diagnosed after some form of morcellation or less than total hysterectomy. Morcellation of a uterine leiomyosarcoma is associated with a worsened outcome. Perri et al. reported a significantly higher recurrence rate and lower overall survival (OS) in women who had undergone something less than a total hysterectomy and subsequently diagnosed with uterine leiomyosarcoma (41). The hazard ratios (HR) for recurrence and survival for TAH compared to other type of resection (myomectomy, morcellation, or supracervical hysterectomy) were 0.39 and 0.36, respectively. Park et al. reported a series in which the 5-year disease-free survival was 40% in women who underwent tumor morcellation and were subsequently diagnosed with leiomyosarcoma, compared to 65% in those with leiomyosarcoma who had not undergone morcellation ($p = 0.04$) (42). Similarly, the 5-year OS was 46% after morcellation compared to 73% in those not morcellated ($p = 0.04$) (42). Morcellation also appears to negatively impact on recurrence risks in cases diagnosed with ESSs, but has no adverse impact on OS (43).

Despite this potential adverse impact of morcellation on outcomes in patients ultimately diagnosed with leiomyosarcoma and endometrial stromal sarcoma, it cannot be stated that morcellation or myomectomy is not appropriate in the management of patients with presumed benign leiomyomas. The risk of leiomyosarcoma and endometrial stromal sarcoma in patients undergoing surgery for presumed benign leiomyoma is quite low. Combining 4 series that had a total of 4,981 patients, the risk of leiomyosarcoma after surgery for presumed benign leiomyoma was only 0.24%, and 0.06% for endometrial stromal sarcoma (44–47). This risk is not greater in those undergoing surgery for a stated indication of “rapidly” enlarging leiomyoma (45).

It is quite reasonable to obtain preoperative pelvic MRI in patients undergoing planned less than total hysterectomy for presumed benign leiomyoma, as it will help localize the tumors as well as provide an excellent negative predictive value. Serum LDH may also be quite useful in helping to determine when morcellation may not be best. However, a patient with a normal serum LDH and/or not suspicious MRI reasonably may be subjected to morcellation with little concern for uterine sarcoma. Morcellation may not be reasonable in patients with highly suspicious MR imaging and elevated serum LDH, as well as in postmenopausal patients with enlarging uterine masses, new uterine masses, or newly symptomatic uterine masses.

STAGING AND PROGNOSIS

Staging Systems

The American Joint Committee on Cancer (AJCC) has a staging system for soft-tissue sarcomas, but there are limitations in applying this to uterine sarcomas. The International Federation of Gynecology and Obstetrics (FIGO) did not have a sarcoma-specific system until recently. A modified system for endometrial carcinomas was most commonly used (18). Zivanovic and colleagues demonstrated that neither the modified FIGO system nor

FIGURE 23.2. Progression-free survival by (A) International Federation of Gynecology and Obstetrics stage and (B) American Joint Committee on Cancer stage. Overall survival by (C) FIGO stage and (D) AJCC stage.
Source: From Zivanovic O, Leitao MM, Iasonos A, et al. Stage-specific outcomes of patients with uterine leiomyosarcoma: a comparison of the International Federation of Gynecology and Obstetrics and American Joint Committee on Cancer staging systems. *J Clin Oncol.* 2009;27:2066–2072, with permission.

the AJCC staging system was adequate (18). Figure 23.2 depicts progression-free and OS based on staging using the modified FIGO and AJCC (18). The concordance indices for PFS using FIGO or AJCC systems were 0.600 and 0.596, respectively, and for OS were 0.620 and 0.633, respectively. These concordance indices are not ideal and are usually >0.700 in more accurate systems. The prognostic inadequacy for both the modified FIGO system and the AJCC system reported by Zivanovic and colleagues at Memorial Sloan-Kettering Cancer Center was further confirmed by investigators at Brigham and Women's Hospital (48).

FIGO devised a uterine sarcoma-specific staging system in 2009 for leiomyosarcoma, endometrial stromal sarcoma, and adenosarcoma (3) (Tables 23.4 and 23.5). Carcinosarcomas are to be staged using the system for endometrial carcinomas (3). There are no clear guidelines on how to stage the other much less common uterine sarcomas. These 2009 FIGO systems for the true uterine sarcomas have not yet been validated. Garg and colleagues reported that the 2009 FIGO system did not provide a more accurate prognostic capability compared to the 1988 system for endometrial carcinomas that was being used for sarcomas prior to 2009 (20). Figure 23.3 depicts the stage distribution for newly diagnosed uterine sarcomas using older staging criteria, which essentially stages any disease beyond the uterine corpus and/or cervix as stage III or IV. The majority of ESSs, leiomyosarcomas, and adenosarcomas present confined to the uterus and/or cervix. Carcinosarcomas and undifferentiated sarcomas have a much greater propensity for metastatic spread at the time of presentation. The value of preoperative imaging to assess for such extrauterine spread has been questioned (51). However, it is still quite reasonable to assess for extrauterine spread preoperatively in patients with newly diagnosed uterine

Table 23.4 2009 FIGO Staging System for Uterine Leiomyosarcomas and Endometrial Stromal Sarcomas

Stage	Definition
I	Tumor limited to uterus
IA	Less than or equal to 5 cm
IB	More than 5 cm
II	Tumor extends beyond the uterus, within the pelvis
IIA	Adnexal involvement
IIB	Involvement of other pelvic tissues
III	Tumor invades abdominal tissues (not just protruding into the abdomen)
IIIA	One site
IIIB	More than one site
IIIC	Metastasis to pelvic and/or para-aortic lymph nodes
IV	
IVA	Tumor invades bladder and/or rectum
IVB	Distant metastasis

sarcomas, since there is still at minimum approximately 25% or greater chance of extrauterine disease (as seen in Figure 23.3), except for adenosarcoma. The other much more rare subtypes tend to present confined to the uterus based on very small case reports and series.

Uterine sarcomas confined to the uterine body (typically stage I) tend to have a worse prognosis than the more common endometrial carcinomas, except for ESSs. The 5-year OS for patients with stage I endometrial stromal sarcoma is approximately 97% (52). The OS is actually excellent for patients with ESSs irrespective of stage. Including all stages of presentation, the OS is approximately 92% (14). This contrasts sharply with the outcomes seen for the other uterine sarcomas. The 5-year OS for adenosarcomas confined to the endometrium is 84%, which is reasonable (3). It drops to approximately 65% if there is any myoinvasion (5). The 5-year OS for leiomyosarcomas, carcinosarcomas, and undifferentiated sarcomas confined to the uterine corpus is 57%, 62%, and 52%, respectively (18,49,52). Patients diagnosed with STUMP previously were considered as low-grade leiomyosarcomas. These patients have an outstanding prognosis and this may have biased earlier publications regarding outcomes in “leiomyosarcoma.”

Nomogram

Improved prognostic systems and methods are needed for uterine sarcomas. Nomograms to provide prognostic and predictive information are being used more commonly in oncology. A nomogram to predict 5-year OS in patients with uterine leiomyosarcomas was developed by investigators at Memorial Sloan-Kettering Cancer Center (53) (Fig. 23.4). A total point score is obtained by adding up the various listed clinicopathologic criteria. This score is then plotted against the 5-year OS line at the bottom to come up with an estimated survival. This

The value of perioperative imaging in patients with uterine sarcomas. *Gynecol Oncol*. 2009;115:37–40, with permission.

nomogram is freely available online at <http://www.mskcc.org/cancer-care/adult/endometrial-other-uterine/leiomyosarcoma/prediction-tools>. The bootstrap-validated concordance probability for this nomogram was 0.65. Although slightly better than current FIGO or AJCC systems, it is still not ideal, and will require further validation and development.

Molecular Prognostics

A possible reason for the limited prognostic capabilities of current staging systems and nomogram is that they rely on anatomic, clinical, and pathologic criteria that have not been consistently associated with outcome. A better molecular understanding of these tumors is urgently needed and may possibly provide greater prognostication. Estrogen (ER) and progesterone (PR) receptor expression in uterine leiomyosarcomas has been reported to be associated with outcome by Leitao and colleagues (54). In their cases presenting with extrauterine disease, including cervical extension alone, ER/PR expression was not prognostic. However, it was prognostic in those with disease confined to the uterine body. Most notably, of the 10 PR overexpressing cases, only one recurred and died compared to 9 of the 10 PR nonexpressing cases having recurred and 5 died (54). Ioffe and colleagues also reported a possible association with hormone receptor expression and outcome in uterine sarcomas (55). Subtyping hormone receptors may provide even further improved prognostication (56). Koivisto-Korander and colleagues assessed the association of immunohistochemical of various proteins (Ki-67, p53, CD10, CD44, desmin, SMA, ER α , and PR-A) with survival outcomes in patients with carcinosarcoma and leiomyosarcoma (57). None of the expression patterns of any of these proteins was associated with survival in patients with carcinosarcoma (57). However, in patients with leiomyosarcoma, only ER α and PR-A overexpression was associated with survival (57).

Expression patterns of other proteins have been reported to possibly be associated with outcome. β -catenin expression was

FIGURE 23.4. Nomogram for 5-year overall survival for uterine leiomyosarcoma. This is the uterine leiomyosarcoma nomogram for 5-year overall survival. The mitotic index (asterisk) was modeled using log transformation; for display purposes, values were converted back to original scale (exponential; concordance probability [CP], 0.671; bootstrap-validated CP, 0.651).

Source: Zivanovic O, Jacks LM, Iasonos A, et al. A nomogram to predict postresection 5-year overall survival for patients with uterine leiomyosarcoma. *Cancer*. 2012;118:660–669, with permission.

associated with crude survival in patients with leiomyosarcoma but not in those with endometrial stromal sarcoma, adenocarcinoma, or undifferentiated sarcoma (58). Cyclooxygenase-2 (COX-2) expression was reported to be independently associated with outcome in patients with leiomyosarcoma (59). Cox-2 was not prognostic in patients with uterine carcinosarcoma (60). P53, p16, Ki67, and bcl-2 expression patterns were all reported to be associated with outcome in patients with leiomyosarcomas, but only bcl-2 was prognostic in undifferentiated and ESSs in a series reported by D'Angelo and colleagues (61). CD10 and PTEN expression were not prognostic in this same report (61). These are all quite interesting hypothesis-generating reports as we begin to unravel the molecular biology of these rare tumors but all require further validation and investigation before we can start to incorporate them into clinically useful prognostic tools. However, improved prognostication will likely come from molecular-based analyses and possibly protein and/or gene expression profiling. Additional descriptions are also provided in the Pathology section of this chapter.

Patterns of Recurrence

The patterns of first recurrence are described in Table 23.6. The median progression-free survival (PFS) (i.e., time to recurrence) is over 100 months (8.3 years) in patients with endometrial stromal sarcoma based on current criteria for diagnosing this tumor (11,13,64,65). Prior studies reported median PFSs of 15 to 23 months for endometrial stromal sarcoma (5,9). However, this probably just reflects the inclusion of what is now considered to be undifferentiated sarcomas and not truly ESSs. Few data exist on patterns of recurrence for undifferentiated sarcomas but it is likely to reflect that seen with the other sarcomas

or what was previously reported for “endometrial stromal sarcomas.” The median time for adenocarcinomas is around 40 months (21). Leiomyosarcomas and carcinosarcomas have a very short median PFS: 12 to 19 months and 11 to 14 months, respectively (5,9,18,20,63,66,67). Extrapelvic recurrences are quite common with 82% of carcinosarcomas involving an extrapelvic site. The most common sites of extrapelvic recurrences are the lungs for ESSs and leiomyosarcomas. The abdomen is the most common extrapelvic site for adenocarcinomas and carcinosarcomas. STUMPS have an exceedingly low risk of recurrence and a nearly 100% OS. Only 3 of 41 STUMP cases treated at MD Anderson Cancer Center recurred (one each at 13, 47, and 68 months) (22). All 41 patients were alive and without evidence of disease at the time of publication (22). The rarity of other uterine sarcomas precludes definitive comments on patterns of recurrence but most tend to recur locally when they do.

MOLECULAR BIOLOGY AND GENETICS

The association with expression patterns of certain proteins and outcome was described above. These are limited and mostly nonvalidated data. The key to improved prognostic and predictive tools as well as therapeutics in patients with uterine sarcomas will only be achieved with a significant understanding of the inherent molecular biology of these tumors, which, in general, is very limited at this time. We will describe some recent molecular studies of particular interest but many more are in publication and we expect more to be forthcoming. Additional descriptions are also provided in the Pathology section of this chapter.

Table 23.6 Patterns of First Recurrence in Patients with Select Uterine Sarcomas

	ESS (11,13,65,66)	AS (21)	LMS (5,9,18,20,67,68)	CS (5,9,64,67)
Median PFS (months)	101–130	41	12–19	11–14
Pelvic only first recurrence ^a	43%	62%	41%	18%
Extrapelvic first recurrence ^b	57%	38%	59%	82%
Most common extrapelvic site	Lung	Abdomen	Lung	Abdomen

PFS, progression-free survival; ESS, endometrial stromal sarcoma (only includes true “low-grade” cases); AS, adenocarcinoma; LMS, leiomyosarcoma; CS, carcinosarcoma.

^a Includes vaginal ± other pelvic recurrence.

^b Some cases also with a concurrent pelvic recurrence.

Frequency of known gene rearrangements in endometrial stromal tumors. *Am J Surg Pathol.* 2011;35:1364–1372, with permission.

Gene rearrangements have been described and validated in patients with ESSs with at least 75% having a gene rearrangement (68). The t(7;17) translocation resulting in the *JAZF1-SUZ12* gene fusion is the most common translocation found in approximately 35% to 50% of ESSs (68). Other noted gene fusions are *JAZF1-PHF1*, *EPC1-PHF1*, *JAZF1* only, and *PHF1* only (68).

Undifferentiated endometrial sarcomas (previously referred to as high-grade ESSs) lack these *JAZF1* based rearrangements but instead appear to frequently harbor the *YWHAE-FAM22A/B* genetic fusion (69,70). The *YWHAE-FAM22A/B* fusion has been proposed as a potential oncogene in the development of undifferentiated (i.e., high-grade ESSs) due to the transforming properties of the *YWHAE-FAM22* protein that is expressed by this gene fusion (69,70). Additionally, the *YWHAE-FAM22A/B* fusion appears to be specific to these tumors since this rearrangement was not detected in 827 other cases representing 55 tumor types (70).

LMP2 is an important immuno-protease subunit that is induced by IFN- γ and suggested to be involved in various cell events, possibly including the suppression of tumor cell growth (71). Mice lacking LMP2 appear to spontaneously develop uterine leiomyosarcomas with an incidence of about 40% at 14 months of age (71). LMP2 expression appears to be absent in human leiomyosarcoma but is retained in human leiomyomata (71). LMP2 may be involved in the sarcomagenesis of uterine leiomyosarcomas and will require continued investigation. Leiomyosarcomas do not seem to harbor somatic mutations in *EGFR*, *CDKN2A*, *MET*, *KIT*, *RAS*, *BRAF*, *PI3KCA*, *HER-2*, or *PDGFR- α* , for which targeted therapies are available (72,73).

Growdon and colleagues analyzed uterine carcinosarcomas for the presence of somatic mutations (73). The rate of mutations identified for each gene analyzed was *PIK3CA* (56%), *KRAS* (44%), *TP53* (33%), *CTNNB1* (6%), and *NRAS* (6%). *TP53* mutation was the only mutational event that retained an independent association with survival. The Akt/ β -catenin pathway and alterations in Rb expression have been suggested to be involved in the development of carcinosarcomas of the uterus (74). This is felt to be modified through transactivation of the *Slug* gene. Cimbaluk et al. assessed immunohistochemical expression of potential therapeutic targets (75). Expression was low in both the epithelial and mesenchymal components

for HER-2 (6% and 0%, respectively) and c-Kit (0% in both). EGFR expression was 30% in the epithelial and 67% in the mesenchymal component. COX-2 was expressed in 70% of the epithelial component but in only 16% of the mesenchymal component. VEGF was highly expressed in both the epithelial (100%) and mesenchymal components (93%).

PATHOLOGY

Malignant mesenchymal tumors can be classified into pure mesenchymal tumors and tumors with a mixed epithelial and mesenchymal components. In the first group, the most common is leiomyosarcoma, followed by ESS, and rarely, others including rhabdomyosarcoma, liposarcoma, angiosarcoma, chondrosarcoma, osteosarcoma, and alveolar soft-part sarcoma. Mixed epithelial and mesenchymal tumors include carcinosarcoma and adenocarcinoma. In addition, there are 3 rare mesenchymal tumors occurring in the uterus that are usually benign but can cause problems in the differential diagnosis with malignant lesions: uterine tumors resembling ovarian sex-cord tumors (UTROSCTs), perivascular epithelioid cell tumors (PEComas), and inflammatory myofibroblastic tumor (76).

Leiomyosarcoma and Other Smooth Muscle Tumors

Leiomyosarcomas are malignant smooth muscle tumors that usually arise *de novo*. Recent studies have shown that some tumors have areas with benign morphology, suggesting some progression from leiomyoma to leiomyosarcoma (77,78), but clonality studies only support this progression in a small percentage of cellular or symplastic leiomyomas (78,79). Leiomyosarcoma is usually a solitary, poorly circumscribed mass with a soft and fleshy consistency. The cut surface is variegated with gray areas intermixed with yellow areas of necrosis and sometimes hemorrhagic areas. The epicenter of the tumor is the myometrium and most leiomyosarcomas are intramural. Occasionally, they can extend into the cervix or beyond the uterus through the serosa (Figs. 23.5–23.7).

FIGURE 23.5. Leiomyosarcoma, gross.

Microscopically, most leiomyosarcomas are overtly malignant and have hypercellularity, coagulative tumor cell necrosis, abundant mitoses, atypical mitoses, marked cytologic atypia, and infiltrative borders (Fig. 23.8). Some cases lack some of these features, and occasionally the differential diagnosis between a benign and a malignant lesion can be controversial. The 3 most important criteria are coagulative tumor cell necrosis, high mitotic rate, and significant cytologic atypia. In conventional type of leiomyosarcomas (spindle cell type), the diagnosis of malignancy is rendered when any 2 of the following 3 criteria are present: tumor cell necrosis, diffuse moderate to severe cytologic atypia, and 10 or more mitoses per 10 high-power fields (HPF) (80). Tumor cell necrosis (TCN) has an abrupt transition from viable to necrotic tissue (Fig. 23.9). In contrast, hyaline necrosis seen in some leiomyomas has an area of hyalinized tissue between the necrotic and viable tumor. Some smooth-muscle tumors have histologic features that are not worrisome enough to render an unequivocal diagnosis of sarcoma. These tumors can be classified as atypical leiomyomas, smooth muscle tumors with low malignant potential (low probability of an unfavorable outcome), or STUMP depending on their histological features. Figure 23.10 summarizes the classification of uterine smooth muscle tumors based on their histologic characteristics. This classification is based in large part upon a large retrospective study from Stanford University published in 1994 (80), the largest to date. Tumors that clinically and pathologically appear to be leiomyomas but have up to 15 mitoses per 10 HPF behave in a benign fashion and are classified

FIGURE 23.6. Leiomyosarcoma, gross, showing heterogenous appearance.

FIGURE 23.7. Leiomyosarcoma, gross, with extension beyond uterus.

as mitotically active leiomyomas (80,81). Leiomyomas are more likely to have a high mitotic count if they are excised during the secretory phase of the menstrual cycle, during pregnancy, or while patients are receiving exogenous progesterone therapy.

Five recent studies in the pathology literature have addressed the diagnosis and clinical behavior of borderline smooth muscle tumors classified as atypical leiomyomas, tumors with low malignant potential and tumors of uncertain malignant potential (22,82–85). The overall recurrence rate based on these 5

FIGURE 23.8. Leiomyosarcoma, microscopic.

FIGURE 23.9. Leiomyosarcoma, microscopic, with abrupt transition from viable to necrotic tissue.

studies is 8.6%. Most tumors recurred as STUMPs, although 1 case recurred as leiomyosarcoma (22). Most patients were alive and free of disease at the time the studies were published, although 1 study reported 3 disease-specific deaths and all with more than 6 years after initial diagnosis (82). There are tumors that lack 1 of the 3 major diagnostic criteria (mitoses, atypia, necrosis) but have other worrisome features such as infiltrative borders, lymphovascular invasion, or atypical mitoses. Classification of such cases is always problematic. It is recommended that these unusual cases be reviewed by a gynecologic pathologist.

Infarcted necrosis of benign leiomyomas can be seen sometimes during pregnancy, after uterine artery embolization, thermal balloon endometrial ablation, therapy with tranexamic acid, or therapy with high-dose progestins. In addition, pedunculated submucosal leiomyomas can undergo spontaneous torsion, and infarction, even with protrusion through the cervix.

Infarcted leiomyomas should not be confused with leiomyosarcoma. The infarcted necrosis is not tumor cell necrosis, as mentioned before. In addition, infarcted leiomyomas are not associated with significant cytologic atypia, high mitotic rate, atypical mitoses, or invasive borders. An accurate clinical history can be very useful in many of these cases.

Several recent studies support the use of immunostains for p16, p53, and Ki67 (proliferative activity marker) in the differential diagnosis of problematic smooth-muscle tumors. p16 is overexpressed in uterine leiomyosarcomas compared with leiomyomas and STUMPs suggesting that p16 may be implicated in the pathogenesis of leiomyosarcomas. In addition, leiomyosarcomas have higher p53 expression and higher proliferative activity (Ki67) than other uterine smooth-muscle tumors. The combination of high p16, p53, and Ki67 expressions is supportive of the diagnosis of leiomyosarcoma if used in combination with H&E features, gross appearance of the tumor, and clinical features (86–89).

Classification criteria of smooth muscle tumors with either myxoid or epithelioid features differ from those used for spindle cell tumors. Epithelioid tumors have cells that are round rather than spindle shaped and have round nuclei mimicking epithelial cells (hence the term “epithelioid”) (Fig. 23.11). Epithelioid leiomyosarcomas have significant cytologic atypia, at least 3 mitoses per 10 HPF, and tumor cell necrosis in 50% of cases (90). At least one previous study suggests that epithelioid tumors may behave more aggressively than spindle-cell tumors and have a higher tendency to metastasize (91). Myxoid leiomyosarcomas are rare and may be histologically deceiving because of lack of tumor cell necrosis, minimal atypia, and a low mitotic rate. The most reliable histologic criteria of malignancy are infiltrative borders and lymphovascular invasion (92) (Fig. 23.12). Myxoid leiomyosarcomas have a similar long-term survival as other leiomyosarcomas, but at least one study reported better 5-year survival (73%) as compared with ordinary leiomyosarcomas (49%) (10).

Histologic parameters of leiomyosarcomas that have been suggested to correlate with a worst prognosis include mitotic rate (93,94), lymphovascular invasion (93), size (94), diffuse high-grade cytologic atypia (95), and negative ER and PR (54).

FIGURE 23.10. Uterine smooth muscle tumors (excluding epithelioid and myxoid types and cervical tumors). AWD, alive with disease; DOD, dead of disease; HPF, high power fields; LMP, low malignant potential; NED, no evidence of disease; SMT, smooth muscle tumor.

FIGURE 23.11. Epithelioid leiomyosarcoma, microscopic appearance.

However, many of these have not been found to be associated with outcome and, therefore, not entirely validated.

Benign metastasizing leiomyoma

Benign metastasizing leiomyoma (BML) is characterized by the presence of a uterine leiomyoma associated with one or more extrauterine smooth muscle tumors histologically benign. The most common site of "metastasis" is the lung, although "metastases" have also been described in the retroperitoneum, mediastinal lymph nodes, soft tissues, and bone. Before rendering the diagnosis of "benign metastasizing leiomyoma" pathologists need to sample the tumors extensively to rule out any aggressive components. The pathogenesis is unclear although some animal experiments suggest that BML may be secondary to lymphatic and hematological spread, coelomic metaplasia, and intraperitoneal seeding (pathogenesis similar to that of endometriosis) (96).

Carcinosarcoma

Uterine carcinosarcomas, also called malignant mixed müllerian tumors, are lesions containing carcinomatous and sarcomatous elements (Fig. 23.13). Numerous studies have shown

FIGURE 23.12. Myxoid leiomyosarcoma, microscopic appearance.

FIGURE 23.13. Carcinosarcoma, microscopic appearance.

that these tumors are clonal malignancies derived from a single stem cell and should be considered "metaplastic carcinomas" (97,98). One study has identified similar mutations signatures in *PIK3CA*, *KRAS* and *NRAS* in the carcinomatous and sarcomatous elements within a given tumor (73).

Most carcinosarcomas are polypoid tumors that fill the endometrial cavity and may protrude through the cervical os (Fig. 23.14). The tumors are soft and fleshy, with areas of necrosis and hemorrhage. Occasionally, they show gross myometrial invasion, and may extend into the cervix. The size of the tumor is quite variable and may range from less than 2 cm to over 20 cm in diameter. Microscopically, the tumors have a typical biphasic pattern with carcinomatous and sarcomatous elements. The carcinoma is usually high-grade and reminiscent of serous carcinoma, although some cases have undifferentiated, endometrioid, clear-cell, or even squamous carcinoma. The sarcomatous component is always high-grade and may be homologous or heterologous. In homologous tumors, the sarcomatous component is usually high-grade fibrosarcoma, although varieties such as leiomyosarcoma, malignant fibrous histiocytoma, or undifferentiated sarcoma may be found as well. Heterologous elements are seen in half of the cases. The most common heterologous sarcoma is rhabdomyosarcoma, followed by chondrosarcoma, and less often osteosarcoma and liposarcoma (99). Most carcinosarcomas have myometrial invasion, most commonly into less than half of the wall (99). Lymphovascular invasion is present in 60% and the carcinomatous element is usually the component invading myometrium and lymphovascular spaces (62,99).

Most studies suggest that the behavior of carcinosarcomas is predicted by the carcinomatous component. Tumors typically metastasize through lymphatic channels similar to endometrial carcinomas. Most metastases and recurrences are composed of pure carcinoma (27,28). Histopathologic adverse prognostic factors include heterologous elements (in stage I tumors), a high percentage of sarcomatous components in the main tumor and in the recurrences, and deep myometrial invasion (27–29).

Müllerian carcinosarcomas may arise in extrauterine-extraovarian sites. Most cases have been reported in the peritoneum, or retroperitoneum. Some cases occur at the site of previous radiotherapy, and some cases arise in areas of endometriosis (100–105).

Endometrial Stromal Neoplasms

In the current World Health Organization classification, endometrial stromal tumors are classified into endometrial stromal

FIGURE 23.14. Carcinosarcomas, gross photographs of 4 cases demonstrating polypoid nature of lesions.

nodules, ESSs (by definition low-grade), and undifferentiated endometrial sarcoma. Both endometrial stromal nodules and ESSs are composed of cells identical to those found in the stroma of proliferative endometrium. Undifferentiated endometrial sarcomas, on the other hand, are high-grade sarcomas that do not resemble endometrial stroma and its diagnosis is made excluding other uterine sarcomas.

The differential diagnosis between an endometrial stromal nodule and an ESS is important since the nodules are always benign. Differential diagnosis is based upon the presence of infiltrating margins with or without angioinvasion in ESS. These 2 features are not seen in stromal nodules, which are always well circumscribed and have pushing margins (106).

Stromal Nodule

Stromal nodules are by far the least common of the pure endometrial stromal neoplasms. They are usually solitary masses with diameter varying from 1.2 to 22 cm with an average of 7.1 cm (107). On cut section, endometrial stromal nodules are fleshy and often tan-yellow. Microscopically, they are composed of uniformly bland, small cells resembling normal endometrial stromal cells with fusiform nuclei and scant cytoplasm. Abundant arterioles, reminiscent of the spiral arterioles of the normal

endometrium, are also present. The mitotic rate is low, with most tumors having fewer than 5 mitoses per 10 HPF. Most endometrial stromal nodules are cellular, and some have variable amounts of intercellular collagen, which occasionally forms dense collagen bands or nodules (Fig. 23.15). Another common finding is the presence of clusters of foamy histiocytes within the tumor. The borders between the tumor and the adjacent myometrium are microscopically well defined (pushing). Occasionally, they may have more irregular borders with minimal areas of tumor extending into adjacent myometrium, usually within 3 mm of the main tumor mass (106). Endometrial stromal nodules lack associated lymphovascular invasion. Other changes that can be seen in endometrial stromal nodules include smooth muscle metaplasia, cystic degeneration, sex-cord-like areas, and necrosis.

Endometrial stromal nodules may be confused with cellular leiomyomas. Since both tumors are benign, the misdiagnosis of one for the other is probably of no clinical consequence in a hysterectomy specimen. In a curettage specimen, the differential diagnosis is more important. There are some histologic features that favor a leiomyoma: blood vessels with thick muscular walls, cleft-like spaces, and merging with the adjacent myometrium. In addition, a battery of immunohistochemical stains may be of use. CD10 is usually present in endometrial stromal cells, and smooth muscle tumors stain positively for desmin and h-caldesmon.

FIGURE 23.15. Endometrial stromal nodule, microscopic appearance.

FIGURE 23.16. Endometrial stromal sarcoma, low-grade, microscopic appearance.

Endometrial Stromal Sarcoma

The last WHO classification divides endometrial sarcomas into 2 categories: ESSs (low-grade by definition), and undifferentiated endometrial sarcomas. However, recent studies have shown that not all ESS are low-grade and favor the subdivision of ESS into 2 categories: low-grade and high-grade, based on histological and molecular characteristics (90). This remains controversial.

The true low-grade ESSs have uniformly bland cells reminiscent of endometrial stromal cells. On gross examination, some are comprised of a single visible mass, and others have multiple masses or diffuse myometrial infiltration by worm-like masses (Fig. 23.16). Typically, these tumors show permeation of the myometrial wall, in some cases up to the serosa (Fig. 23.17). Most tumors have fewer than 10 mitoses per 10 HPF. Some ESSs have unusual histologic features that may confound the diagnosis. These features include myxoid changes, fibroblastic and/or smooth muscle differentiation, epithelioid changes, and extensive endometrioid glandular differentiation (108–111).

Low-grade ESSs are usually positive for ER, PR, and CD10, and approximately 50% have cytogenetic abnormalities involving rearrangements of chromosomes 6, 7, and 17. The most characteristic translocation of these tumors, t(T7;17) (Tp15;q21), generates a fusion of the *JAZF1* and *JJAZ1* genes. The presence of this chromosomal abnormality may be of use in the diagnosis of difficult cases or recurrent tumors (112).

The newly described entity of “high-grade ESS” is composed of tumors that display “either (1) a combination of low-grade and undifferentiated areas; (2) cytologic and immunohistochemical features that are intermediate between classic low-grade ESS and undifferentiated endometrial stroma (UES), or (3) cytologic features of UES but with the presence of finger-like infiltrative pattern of the surrounding myometrium or extension into lymphovascular spaces” (90). High-grade ESSs have been so far only described in the uterine corpus and they ranged in size from 3 to 9 cm (median, 7.5 cm). All tumors diffusely infiltrate myometrium, and have vascular invasion (90). These tumors have more nuclear atypia and mitoses than low-grade ESS, and can have necrosis, which is not seen in low-grade tumors. In addition, they have a characteristic gene *YWHAE-FAN22* rearrangement that is never present in true low-grade ESS. High-grade ESS can often be negative for ER and PR and have a worst prognosis than low-grade ESS, although they are not as aggressive as UES (90). Unlike low-grade ESS, high-grade ESS are often negative for ER, PR, and CD10 (90). This new distinct entity and whether

different from undifferentiated endometrial stromal sarcoma requires further validation.

Low-grade ESSs may occur in extrauterine sites including ovary, fallopian tube, cervix, vagina, vulva, pelvis, abdomen, retroperitoneum, placenta, sciatic nerve, or round ligament (113–118). Some of these cases are associated with endometriosis. Histologically, they are similar to uterine ESSs, and a uterine

FIGURE 23.17. Endometrial stromal sarcoma, low-grade, gross appearance.

tumor needs to be excluded before accepting the lesion as a primary extrauterine ESS. The relapse rate for extrauterine ESS is 62%, which is similar to that of advanced low-grade uterine ESS.

Undifferentiated endometrial sarcomas are rare and account for only 6% of all uterine sarcomas (10). They have cytologic atypia to the extent that they cannot be recognized as arising from endometrial stroma. Morphologically, these high-grade lesions resemble undifferentiated mesenchymal tumors and behave as high-grade sarcomas (10,61,119). It is advisable to use a term such as “high-grade sarcoma,” “undifferentiated sarcoma,” or “poorly differentiated uterine sarcoma” (119) rather than “endometrial stromal sarcoma.” This last term may inaccurately suggest an indolent tumor. Undifferentiated uterine sarcomas are usually seen in patients older than 50 years, have a recurrence rate of over 85%, and are usually fatal (10,61,119).

Müllerian Adenosarcoma

Müllerian adenosarcomas are mixed müllerian tumors composed of malignant stroma and benign epithelium. Most adenosarcomas arise in the endometrium and, rarely, in the endocervix, lower uterine segment, and myometrium (21). Grossly, the majority are solitary polypoid masses with a spongy appearance secondary to the presence of small cysts. Occasional cases appear as multiple polyps or masses and can be multicentric. Their size is variable, being from 1 to 17 cm (mean, 5 cm).

Microscopically, the tumors have a benign epithelial component usually covering the surface of the polyps and in the form of benign glands uniformly distributed throughout the tumor. The mesenchymal component is usually a low-grade sarcoma that resembles endometrial stroma. The presence of hypercellular stroma around the glands is common, and some tumors have a leaf-like papillary growth pattern (Fig. 23.18). Sometimes the diagnosis of adenosarcoma may be difficult because of the very low-grade nature of the sarcoma. Minimal criteria were described by Clement and Scully in a review of 100 cases of adenosarcoma published in 1990 (21). They include at least one of the following: two or more stromal mitoses per 10 HPF, marked stromal hypercellularity, and significant stromal cell atypia. Even with these criteria, some cases are deceptively bland, and several cases have been seen in which the diagnosis was only possible after multiple “recurrences” of uterine polyps were reviewed (120). A minority of cases have “sarcomatous

overgrowth,” when more than 25% of the tumor is composed of pure sarcoma. In these cases, the sarcoma is typically high-grade and the lesions are aggressive (121) (Fig. 23.19).

Most adenosarcomas without stromal overgrowth express estrogen and progesterone receptors in the sarcomatous component and this may be used for therapeutic purposes. However, hormonal receptors are negative in adenosarcomas with stromal overgrowth (120,122). Besides stromal overgrowth, the only other histopathological feature associated with decreased survival is myometrial invasion (21,49,120,121). Müllerian adenosarcomas have been described in extrauterine sites including the ovary and areas of endometriosis in the vagina, rectovaginal septum, gastrointestinal tract, urinary bladder, pouch of Douglas, peritoneum, and liver (123–131).

Uterine Tumor Resembling Ovarian Sex-Cord Tumor

In 1976, Clement and Scully (132) coined the term uterine tumors resembling ovarian sex-cord tumors (UTROSCTs) to describe a series of uterine neoplasms with sex-cord-like pattern. Since then, sex-cord-like patterns have been demonstrated in endometrial stromal neoplasms, smooth-muscle neoplasms, and in cases lacking clear endometrial stroma and smooth-muscle differentiation. The term UTROSCT should be reserved for this last category. UTROSCT are tumors of uncertain histogenesis/lineage. Immunohistochemically these tumors co-express epithelial, myoid and sex-cord markers (133,134). This immunoprofile can also be seen in ESSs with sex-cord-like areas. However, UTROSCT lack the typical *JAZF1-JJAZ1* translocation frequently seen in endometrial stromal tumors (135). UTROSCTs are rare tumors, usually submucosal and well circumscribed, with a yellow cut surface. Histologically, they are composed of sertoliiform tubules with low mitotic activity and little nuclear atypia (132–134) (Fig. 23.20). Most of these tumors behave in a benign fashion, although there is at least one reported case with a small bowel metastasis (136).

Perivascular Epithelioid Cell Tumors

Perivascular epithelioid cell tumors (PEComas) are rare neoplasms presumably derived from perivascular epithelioid cells that coexpress melanocytic and smooth muscle markers. Other tumors that belong to the same family include angiomyolipoma

FIGURE 23.18. Müllerian adenosarcoma, microscopic appearance.

FIGURE 23.19. Müllerian adenosarcoma with sarcomatous overgrowth, microscopic appearance.

FIGURE 23.20. Uterine tumor resembling ovarian sex-cord tumor (UTROSCT), microscopic appearance.

(AML), clear-cell/sugar tumor of the lung, lymphangioleiomyomatosis (LLM), and myelomelanocytic tumor of ligamentum teres/falciform ligament. PEComas have been described in a variety of locations including visceral organs, soft tissues, skin, oral mucosa, orbit, and base of skull (137). Uterus and gastrointestinal tract are the most common locations for visceral PEComas. About 8% of PEComas occur in patients with the tuberous sclerosis complex. Most uterine PEComas are histologically and clinically benign. They can be either grossly well-circumscribed or focally infiltrative masses. Histologically, they are composed of epithelioid cells with clear or eosinophilic cytoplasm, sometimes associated with spindle cells, and a prominent vasculature (137,138). Approximately 25% of reported cases developed metastases and/or recurrences. Most malignant tumors have more than one of these three histologic features: necrosis, mitoses > 2 per 50 HPF, and lymphovascular invasion, but there is not a single reliable prognostic indicator other than the presence of lymphovascular invasion (137,138,139).

A distinct subset of PEComas, including some uterine, harbor *TFE3* gene fusions, and show immunoreactivity for TFE3 protein (140). In the past, *TFE3* gene fusions had only been described in alveolar soft-part sarcomas and some renal-cell carcinomas. PEComas with *TFE3* gene fusions appear to occur in younger people without tuberous sclerosis.

Inflammatory Myofibroblastic Tumor

Inflammatory myofibroblastic tumors (IMT) are indolent mesenchymal lesions that usually behave in a benign fashion or may recur locally. Most common sites include lung, mesentery, omentum, and retroperitoneum. Few cases have been reported in the uterus (141,142) where they present as polypoid masses in the lower uterine segment or bulky myometrial masses. They range in size from 1 to 12 cm. They are composed of bland spindle cells, with less than 2 mitoses per 10 HPF and no necrosis. Immunohistochemical expression of ALK is characteristic of all IMTs and can be used in the differential diagnosis with other uterine spindle-cell tumors that are negative (including smooth-muscle tumors, ESSs, and carcinosarcomas)(141).

Other Rare Uterine Sarcomas

Rarely other sarcomas can be found in the uterine corpus. Rhabdomyosarcomas, although more common in the cervix of

children, have also been encountered in the corpus in adults. They can be of embryonal or pleomorphic histology. They are aggressive tumors with a 5-year disease-specific survival of only 29%. Patients with pleomorphic rhabdomyosarcoma have a worse prognosis than those with embryonal histology (10,143,144). Uterine liposarcomas are rare tumors. Some of them arise in uterine lipoleiomyomas (145), and others are associated with smooth-muscle tumors and may represent leiomyosarcomas with cyst divergent differentiation (144,146). Other rare sarcomas described in the uterus include angiosarcoma, Ewing sarcoma, alveolar soft-part sarcoma, osteosarcoma, chondrosarcoma, fibrosarcoma, and malignant fibrous histiocytoma (144).

SURGERY

Surgery is a cornerstone in the treatment of the majority of soft-tissue sarcomas, including uterine sarcomas. Many women with uterine sarcomas will be premenopausal at the time of initial diagnosis and concerns about fertility and premature menopause need to be considered. Surgery to remove the primary tumor, myomectomy, or most often a hysterectomy, as well as to inspect the peritoneal cavity, is central in the initial management of these patients. The need to perform nodal evaluations, nodal dissections, and removal of the ovaries will be discussed. The role of cytoreductive procedures of extrauterine disease at the time of diagnosis and at recurrence will also be discussed. Fertility-preserving options are extremely limited, unfortunately, but they are possible in a few highly select cases of the less aggressive mesenchymal tumors.

Uterine Preservation

Myomectomy, or tumor resection, with preservation of the uterus is an option in younger women who wish to preserve fertility and are diagnosed with STUMP or other atypical leiomyomata of the uterus. Unfortunately, a total hysterectomy (never supracervical) must be performed in the majority of malignant mesenchymal tumors of the uterus. There is no clear option to preserve the uterus in patients diagnosed with leiomyosarcoma, undifferentiated (or high-grade) ESS, or carcinosarcoma. Uterine preservation has been described in 8 women diagnosed with “leiomyosarcoma,” and successful pregnancies were reported (147). However, it is unclear from this report whether these were all truly “high-grade” leiomyosarcomas or whether some, or all, were STUMPs or other less malignant histologies (147). A total hysterectomy must still be recommended until significant further investigation is conducted and reported.

Endometrial stromal tumors are a little challenging. A confirmed endometrial stromal nodule would not require completion hysterectomy since it is a benign lesion. However, it is difficult to confirm whether such a tumor is only an endometrial stromal nodule or an ESS without a significant amount of normal myometrium around it to confidently state that there are no infiltrating margins with or without angioinvasion (106). Therefore, a total hysterectomy should be recommended in postmenopausal women and in women who have completed childbearing. However, it may also still be necessary in women who may wish to have children. Uterine preservation for ESS has been reported in a very young 16-year-old girl (148) and in a 25-year-old who went on to carry a successful pregnancy (149).

Role of Nodal Evaluation or Lymphadenectomy

Two important questions to ask when deciding about whether to perform a procedure, in particular nodal dissections of

nonenlarged lymph nodes and removal of ovaries in premenopausal women, are (a) what is the risk of microscopic disease in those organs, and (b) is there a benefit to removing those organs. Lymph node metastasis in adult soft-tissue sarcomas is <3%, with some variation among histologic subtypes (150). Routine regional lymphadenectomy is not recommended for patients with adult soft-tissue sarcomas, but resection of bulky isolated metastases is considered (150).

The risk of lymph metastasis in leiomyosarcoma overall is approximately 7% (4,5,27,50,151,153) (Table 23.7). However, the rate of occult lymph node metastasis is less than 3% (151–154). There is no clear benefit to routine lymphadenectomy in patients who present with uterine leiomyosarcoma with disease confined to the uterus and/or clinically normal lymph nodes (4,16,27,50,151). Carcinosarcomas have a higher rate of both overall (27%) and occult (20%) lymph node metastasis (4,5,19,49,62,152) (Table 23.8). Undifferentiated endometrial sarcomas are also felt to behave similarly, but clear data are lacking. The role of lymphadenectomy beyond debulking of enlarged lymph nodes remains to be determined. Nemani and colleagues suggested that there is a benefit to lymphadenectomy irrespective of the use of radiotherapy (158). However, the current standard is that all patients, irrespective of stage, receive adjuvant systemic chemotherapy. It is quite possible that the therapeutic benefit of lymphadenectomy, if any, in patients with carcinosarcomas may be tempered by this. Nodal dissection in patients with carcinosarcoma is still reasonable and considered “standard.” The rate of overall and occult lymph node metastasis in ESS is 16% and 6% (4,5,13–15,154–157) (Table 23.9). Deep myometrial invasion and extensive lymph–vascular space invasion (LVSI) further increase the risk of occult metastasis (15). Both of these features are often not available at the time of hysterectomy. There is no clear known survival advantage to routine lymphadenectomy in these patients (14). It is reasonable to consider lymphadenectomy at the time of hysterectomy,

Table 23.7 Lymph Node and Ovarian Metastases in Uterine Leiomyosarcoma

^aOccult metastasis means nodal metastasis in clinically normal lymph nodes and disease clinically confined to the uterine corpus and/or cervix.

recognizing the therapeutic, prognostic, or predictive value of this in ESS is unknown. Reoperation to complete a lymphadenectomy is not likely to be of any benefit in patients with ESSs that do not exhibit deep stromal invasion and extensive LVSI. The rate of lymph node metastasis in adenocarcinomas is approximately 3% (49). Based on very limited information, lymphadenectomy in patients with otherwise disease clinically confined to the uterus may not offer much benefit.

Role of Oophorectomy

The risk of ovarian metastasis is very low in leiomyosarcoma (152,153) (Table 23.7). Routine oophorectomy, especially in premenopausal patients, provides no benefit. A SEER analysis actually suggested a worse survival in cases that underwent a bilateral salpingo-oophorectomy (16). It is not entirely clear why removal of the ovaries would lead to a worse prognosis, but at least these data support retaining the ovaries in premenopausal women who are highly desirous of retaining ovarian function. Occult ovarian metastasis can be seen in approximately 12% of carcinosarcomas (152) (Table 23.8). Bilateral salpingo-oophorectomy should be recommended in these patients and fortunately, many will be postmenopausal. Occult ovarian metastasis in ESS is rare (15) (Table 23.9). However, ovarian preservation appears to be associated with a higher risk of recurrence but has no impact on OS since these patients do very well in general (11,14,52). Bilateral salpingo-oophorectomy is recommended because of this recurrence risk reduction but should be carefully discussed in young premenopausal women. The risk of ovarian metastasis and therapeutic benefit is difficult to discern due to a lack of large series addressing this in the other rare uterine sarcomas.

Cytoreductive Surgery for Patients with Extrauterine Disease at Initial Diagnosis

Cytoreductive surgery in patients with uterine sarcoma at the time of presentation has not been well described. The only information available is in patients presenting with uterine leiomyosarcoma and extrauterine metastasis (159). The median PFS in patients with a complete gross resection was 14.2 months,

^aOccult metastasis means nodal metastasis in clinically normal lymph nodes and disease clinically confined to the uterine corpus and/or cervix.

compared to 6.8 months for those who underwent surgery and with visible residual disease ($p = 0.002$) (159). Similarly, OS was 31.9 months compared to 20.2 months, respectively ($p = 0.04$) (159). On multivariate analysis, complete surgical cytoreduction maintained an independent association with PFS but not with OS. However, the lack of independent statistical association with OS might be explained by the relatively small number of cases. Surgical cytoreduction may be a consideration in highly select cases in which complete resection of tumor is felt to be feasible without extensive procedures, such as exenteration. Any potential benefit of surgery should be weighed against the potential risks and these cases are to be individually managed.

Surgery for Recurrent Disease

Data are limited in regard to surgical cytoreduction of recurrent uterine sarcomas. Surgical cytoreduction is considered though in many of these cases especially if there has been a relatively long disease-free interval and sites of recurrence that seem amenable to a complete surgical resection. Surgery is often considered for recurrent ESSs due to their relative indolence, long disease-free intervals, and lack of other effective treatments. The approach to carcinosarcomas often is extrapolated from data for endometrial carcinomas currently. Resection of recurrent leiomyosarcoma has been described. Surgery for the other rare sarcomas is often a consideration, but there is no data for these other very rare uterine sarcomas.

Khoury-Collado et al. described a modern updated series of patients with uterine cancers that developed a recurrence in the pelvis after prior radiation therapy and underwent a pelvic exenteration from 1997 to 2011 (160). There were 6 uterine sarcomas among the 21 included cases: carcinosarcoma ($n = 2$), adenosarcoma ($n = 2$), leiomyosarcoma ($n = 1$), and ESS ($n = 1$). The 2 cases with carcinosarcomas had a short time from prior therapy to exenteration, and the median survival

after exenteration was only 6 months. The median survival after exenteration for the 4 other sarcomas was not reached and the 5-year OS was 66%. Pelvic exenteration seems to be a reasonable consideration in patients with isolated pelvic recurrences after prior radiotherapy. However, it must be recognized that pelvic exenterations are quite morbid and the outcomes reported are based on very small number of highly selected uterine sarcomas.

Resection of pulmonary metastases, both at the initial diagnosis and at the time of recurrence, is often considered in patients with soft tissue sarcomas and associated with a favorable survival benefit (161). Resection of pulmonary metastases specifically of recurrent uterine sarcomas without other extra-thoracic disease is associated with a survival benefit (162). Levenback and colleagues reported 5-year survival rate of 43% after pulmonary metastases resection among a group 45 uterine sarcomas including 38 leiomyosarcomas, 4 ESSs, and 3 carcinosarcomas (162). Unilateral pulmonary recurrences had a better survival after metastatectomy than patients with bilateral recurrences (mean survival 39 months vs. 27 months, respectively [$p = 0.02$]). Tumor size, use of adjuvant therapy after resection, histologic type, age, and time from hysterectomy to first pulmonary resection were not statistically associated with survival after metastatectomy.

Surgical cytoreduction of recurrent uterine leiomyosarcoma with or without pulmonary recurrences has also been reported to possibly provide a survival benefit. Leitao and colleagues reported a survival benefit with optimal (defined as largest residual tumor mass diameter ≤ 1 cm) resection of pulmonary and extrapulmonary first recurrences of uterine leiomyosarcoma (67). The median survival was 3.9 years after an optimal resection compared to only 0.7 years after suboptimal resection ($p = 0.002$). The only other prognostic factor was the time to first recurrence. The median survival was 5.1 years in cases with a time to first recurrence >12 months compared to 1.5 years for those with a time to recurrence of ≤ 12 months ($p = 0.005$). Tumor grade, thoracic versus nonthoracic procedures, sites of first recurrence, and use of adjuvant therapy after resection were not associated with survival. Secondary cytoreduction in these patients with recurrent uterine leiomyosarcoma was also reported to be associated with a survival benefit by Giuntoli et al. in a larger series (163). Secondary cytoreduction to no gross residual was independently associated with survival after adjusting for site of recurrence, use of chemotherapy, radiation therapy, combined surgery and chemotherapy, and recurrence time (163). Similar to Leitao et al., a longer time to recurrence was also prognostic of outcome but with 6 months used of the cutoff (163).

RADIATION THERAPY

Since the use of radiation therapy for patients with uterine sarcomas has been almost exclusively delivered in the postoperative setting (164), the role of preoperative, primary, or palliative radiotherapy will not be presented in this section. As they are more fully discussed in the chapter on epithelial tumors of the corpus, a detailed discussion of the techniques and complications of adjuvant radiation therapy will also not be presented in this chapter.

Uterine Sarcomas

There has been one published phase III randomized trial for all surgically staged patients with stage I and II uterine sarcomas. This study opened in July 1988 and closed to patient accrual in July 2001. Eligible patients underwent an initial

surgical resection that involved mandatory total abdominal hysterectomy and bilateral salpingo-oophorectomy. Retroperitoneal lymph node dissection was optional (only approximately 25% underwent lymph node sampling). Due to the time period of the inception of this trial, there were no recommendations regarding either collection of peritoneal washings or omentectomy. The study enrolled 224 patients for randomization from 36 institutions. Patient histologies included the following: 99 leiomyosarcomas (LMS), 92 carcinosarcomas (CS), 30 ESSs, 1 myxoid leiomyosarcomas, and 2 unclassified cell types. It must be noted that there was a central pathology review of tumor samples. Eligible study patients were randomized to undergo either observation or pelvic postoperative radiation therapy (PORT), which consisted of the delivery of approximately 50.4 Gy total dose in 28 daily 1.8 Gy fractions over 5 to 6 weeks. Conventional radiotherapy techniques using 2-dimensional (2-D) treatment planning techniques involving bony landmarks were employed to treat the whole pelvis as follows: (a) cranially, the superior aspect of the fifth lumbar vertebra; (b) caudally, the inferior aspect of the obturator foramen; (c) anteriorly, the upper margin of the symphysis pubis; and (d) posteriorly the level separating the second and third sacral vertebrae. Treatment field arrangements varied from 3 fields, 4-field “box” (55%), or parallel opposed pair (40%) beams. Chemotherapy was not administered to any study patients (165).

The primary objective of this European Organisation for Research and Treatment of Cancer (EORTC) trial was to determine whether adjuvant pelvic PORT could reduce the local (vaginal) and/or regional (pelvic) relapse rate of study patients versus those receiving no adjuvant therapy along with assessing if improvement in locoregional (LR) control translated in a significant reduction in distant metastases. Secondary objectives of EORTC 55874 focused on the impact of PORT on improving OS and PFS without significant increase in patient toxicity compared to the observational group (165).

EORTC 55874 was originally planned to accrue 75 patients per year for 3 years to obtain the projected 77 LR failures necessary to conduct the statistical analyses. However, due to slow accrual of patients, 2 unplanned interim analyses, the first in April 1995 and the second in December 2001, were required to assess the feasibility of completing study objectives. Thus, it required 13 years (median follow-up of 6.8 years) for patient accrual to record 68 out of the originally planned 77 LR relapses needed for adequate statistical evaluation. Of the 224 enrolled patients, 219 (2 in the observational cohort, 3 in the PORT group) had adequate follow-up data available for analysis (165).

Crude relapse rates for all cell types in EORTC 55874 were 47% (52 out of 110) in the PORT cohort and 50% (54 out of 109) in the observational arm. There was a significant reduction in overall LR relapse in the PORT group of 24 (21%) versus 44 (40%) in the no-adjuvant treatment arm ($p = 0.004$). Furthermore, there was a reduction in isolated LR relapse of 3% in the PORT group versus 18% in the nonirradiated arm. Distant metastases occurred as some component of failure in 49 (46%) of PORT patients versus 35 (32%) of observational patients. In addition, there was a higher isolated distant metastatic rate of 25.5% in the adjuvant group versus 10% in the nonirradiated cohort. The primary cause of death for study patients in EORTC 55874 was malignant disease in 81% (39 out of 48) of PORT patients and 93% (43 out of 46) for observational patients. There was no significant difference in OS or PFS as well as no difference in toxicity assessments between the PORT and observational groups (165) (Figs. 23.21 and 23.22).

Regarding patients with uterine CS, PORT did reduce LR failures from 47% (observational group) to 24% (PORT cohort) for patients with CS ($p < 0.05$), while not significantly increasing the overall distant metastatic rate (29% observational group vs. 35% PORT cohort). This improvement in LR control with adjuvant pelvic PORT was further noted when evaluating patients

FIGURE 23.21. Disease-free survival from EORTC 55874 comparing postoperative radiation therapy versus observation in patients with uterine sarcoma.

Source: From Reed NS, Mangioni C, Malmstrom, et al. Phase III randomized study to evaluate the role of adjuvant pelvic radiotherapy in the treatment of uterine sarcomas stages I and II: An European Organisation for Research and Treatment of Cancer Gynaecological Cancer Group Study (protocol 55874). *Eur J Cancer*. 2008;44:808–818, with permission.

having isolated LR failures (24% observational group versus 4% PORT cohort). However, there were more with isolated distant failures in the adjuvantly irradiated subset of patients with CS (7% observational group versus 15% PORT cohort) (165). This latter finding is similar to what has been shown for patients with endometrial carcinomas randomized to receiving adjuvant pelvic external beam radiation therapy versus the cohort not receiving any external beam irradiation (166). Nevertheless, EORTC 55874 seems to suggest that pelvic PORT should be considered as adjuvant therapy to improve the LR control in patients with stage I and II uterine CS. More importantly, PORT was beneficial to the OS of CS patients when compared to those receiving no adjuvant radiotherapy (HR, 1.58; 95% CI, 0.83, 3.01) (165).

Concerning patients with uterine LMS, the LR relapses in the observation group of 24% were comparable to the adjuvantly irradiated cohort of 20%. Yet, the overall distant failures rate of 33% in the observational group was less than the 54% rate found in the PORT cohort. However, isolated LR failures were 14% in the observational group versus 2% in the PORT cohort. Regarding isolated distant failures, there were 14% in the observational group versus 36% in the PORT cohort (165). Thus, EORTC 55874 may be used to defer adjuvant PORT for patients with stage I and II uterine LMS. Due to the observed

impact on improving isolated LR control in this patient subset population, one could make the argument for employing pelvic PORT as a salvage or palliative modality of therapy for selected patients with early-stage uterine LMS. Finally, EORTC 55874 showed a negative impact of PORT on OS in the LMS cohort (HR, 0.64; 95% CI, 0.36, 1.14) (165).

Most of the published papers on sarcomas of the uterus have been retrospective in nature, often requiring many years, if not decades, to accumulate enough patients to perform meaningful statistical analyses. Furthermore, these studies have often had to combine different cell types of sarcomas to attain numbers sufficient for evaluation (167–179). These retrospective studies have not achieved statistical power to reach definite conclusions.

However, the data from the nonrandomized review of the Surveillance, Epidemiology, and End Results (SEER) analyses of 2,677 cases of uterine sarcoma did demonstrate a statistically significant improvement in survival favoring adjuvant radiotherapy over observation for stage II, III, and IV (but not stage I) uterine sarcomas (26). The use of adjuvant PORT versus observation to significantly improve outcome, including OS, for advanced cases of uterine sarcoma (stages III and IVA) has been further supported in a retrospective single institutional study of 76 evaluable cases of uterine sarcomas (180). Yet, another SEER analysis of 1,819 patients with stage I/II uterine CS and

FIGURE 23.22. Cumulative incidence of locoregional recurrence (**A**) and distant metastases (**B**) of postoperative adjuvant radiation therapy vs. observation in patients with uterine sarcoma. Source: From Reed NS, Mangioni C, Malmstrom, et al. Phase III randomized study to evaluate the role of adjuvant pelvic radiotherapy in the treatment of uterine sarcomas stages I and II: An European Organisation for Research and Treatment of Cancer Gynaecological Cancer Group Study (protocol 55874). *Eur J Cancer*. 2008;44:808–818, with permission.

1,088 with stage I/II uterine LMS revealed an improved survival for the subset of patients with CS who did not have any nodal sampling. However, there was no observed significant survival benefit for CS patient having a node dissection or for any subset of patients with LMS (181).

Recently, a retrospective review of the largest number to date of patients with uterine sarcoma was published (182). A query of the National Oncology Database (NODB) owned by Impac Medical Systems (Sunnyvale, CA) by these latter investigators yielded 3,650 evaluable patients with a diagnosis of uterine sarcomas. Of this initial group, 2,206 had definitive surgery; of these, 1,128 had CS, 529 LMS, and 361 EES comprising stages I through IV (and approximately one-third unknown stage). Statistical analyses showed no significant impact on OS for patients receiving predominantly pelvic PORT (with or without vaginal brachytherapy) versus those receiving no adjuvant therapy. However, it must be pointed out that there was again a noted significant reduction in LR relapse in the adjuvantly irradiated cohort versus the no treatment group of 53% at 5 years ($p < 0.001$). In addition, this LR control benefit of adjuvant radiation versus observation was preserved on subset analyses of patient with uterine CS ($p < 0.001$), LMS ($p < 0.01$) and ESS ($p < 0.05$) (182). Therefore, this latter study may be cited as evidence for future trials to prospectively incorporate adjuvant “volume-directed” radiation therapy into the discussion of potential therapeutic modalities to treat for patients with uterine sarcomas.

The GOG previously conducted 2 prospective clinical trials involving selected patients with uterine sarcomas. The earliest study reported on 156 evaluable patients with surgically staged I or II sarcomas of the uterus (183). Patients were enrolled from 1973 to 1982 and randomized (GOG protocol 20) to receive either at least one cycle of adjuvant doxorubicin or no adjuvant chemotherapy. Prior to study randomization, patients could receive *optional* adjuvant radiotherapy either preoperatively (external pelvic treatment of 40 Gy in 4 to 5 weeks with intracavitary vaginal brachytherapy of 20 Gy to point A) or postoperative pelvic external beam irradiation alone to 50 Gy in 5 to 6 weeks (184).

It should be noted that 11 of 48 (23%) patients with leiomyosarcomas in GOG 20 underwent adjunctive radiotherapy. Forty-nine of 109 patients (45%) with “nonleiomyosarcomas” (85.3% were carcinosarcomas) had adjuvant external beam therapy of the pelvis. Radiotherapy did not seem to affect recurrence in general. Table 23.10 shows that there was a notable decrease in vaginal recurrences in patients with early-stage uterine carcinosarcomas. Table 23.10 also demonstrates an increase in extravaginal failures in the group of patients with CS receiving radiotherapy (183). Table 23.11 depicts additional data from GOG 20 that demonstrate a significant reduction in pelvic relapses (10%) in treated patients compared with those

untreated patients with predominantly uterine carcinosarcomas (23%) (184).

The second main GOG trial (GOG Protocol #40) for patients with uterine sarcomas involved a nonrandomized clinicopathologic evaluation of patients with clinical stage I and II disease uterine LMS and CS (152). This study opened in February 1979 and subsequently closed in October 1988. Of the 453 eligible patients, 430 (95%) had the mandated extrafascial hysterectomy, bilateral salpingo-oophorectomy, and selective retroperitoneal lymphadenectomy. Of this latter group, there were 301 (70%) patients with carcinosarcomas, of which 240 (80%) had surgical stage I/II disease. From this subset, Table 23.12 displays the locations of first sites of relapse(s). Although adjuvant pelvic external beam therapy was not mandated in this surgical trial, there again appears to be a possibility that postoperative pelvic PORT plays a role in reducing LR relapses in patients with early-stage uterine CS.

In a novel pilot study from France, 18 patients with uterine sarcomas with optimally debulked surgical stage I, II, and III sarcomas (13 of 18 with uterine LMS) received adjuvant doxorubicin, cisplatin, and ifosfamide (three cycles) followed by sequential pelvic external beam radiotherapy to a total dose of approximately 45 Gy in 5 weeks with or without vaginal brachytherapy (185). These investigators then performed a matched case-control study utilizing 18 patients of whom 16 underwent pelvic radiotherapy alone and 2 received no adjuvant treatment. With a median follow-up of 43 months (range, 23 to 56 months), this study found that only 5 patients (27.8%) had suffered recurrences. All failed solely in extrapelvic sites. Moreover, neither median survival nor disease-free survival had

been reached for study patients at last follow-up. Thus, there is still much uncertainty regarding the role of pelvic external beam irradiation for patients with uterine LMS, especially reserving “volume directed” radiotherapy in combination with chemotherapy as adjunctive treatment or even as a part of salvage and/or palliative therapeutic intervention.

Uterine Carcinosarcomas

Regarding published reports on individual uterine sarcoma histologies, the most common type is currently being termed as metaplastic carcinomas (97), “mixed epithelial and stromal tumors of the uterus” (2), or historically known as uterine carcinosarcomas or some variant of mixed müllerian uterine tumors (169, 186–195). There has been one randomized phase III prospective trial of adjuvant radiotherapy in carcinosarcomas, (GOG 150). This study compared whole-abdominal irradiation to 3 cycles of cisplatin-ifosfamide chemotherapy with respect to recurrence rates, and DFS and OS. Also evaluated were therapeutic toxicities. Eligible were patients with carcinosarcomas confined to the abdomen who underwent optimal surgical debulking with no postsurgical residual disease greater than 1 cm. Patients randomized to receive radiotherapy were prescribed a total dose of 30 Gy to the whole abdomen using external beam therapy followed by a pelvic boost to an approximate cumulative pelvic dose of 50 Gy.

The first published report of the 2 treatment cohorts was based upon an analysis performed in December 2005 (196). There were 224 patients enrolled, of whom 206 were evaluable. In this latter group, 105 patients underwent adjuvant radiotherapy, while 101 were given chemotherapy. The estimated death rate for patients receiving chemotherapy was 32.8% lower than for those receiving radiotherapy ($p = 0.042$). A subsequently published update of GOG 150 based upon a May 2006 analysis demonstrated that this reduction in estimated death rate by chemotherapy was 31% relative to radiotherapy ($p = 0.046$) (197).

The most recent evaluation of the data of patients on GOG 150 occurred in November 2006 (198). At the time of this analysis, the median duration of follow-up for patients alive at last contact was 63 months. The breakdown of surgical stages for patients in the radiotherapy versus chemotherapy arms is as follows: stage I—35 out of 105 (33.3%) versus 29 out of 101 (28.7%); stage II—11 out of 105 (10.5%) versus 15 out of 101 (14.9%); stage III—45 out of 105 (42.9%) versus 47 out of 101 (46.5%); and stage IV—14 out of 105 (13.3%) versus 10 out of 101 (9.9%). The estimated crude probability of relapse within 5 years was a nonsignificant 58% versus 52% for the radio- and chemotherapy groups, respectively. The sites of first failure are presented in Table 23.13. Although not statistically significant, there were fewer vaginal but more abdominal relapses in the adjuvant radiotherapy group as compared to the chemotherapy arm. Table 23.14 demonstrates that the estimated 5-year survival was approximately 35% for those randomized to adjuvant radiotherapy versus 45% for those receiving chemotherapy. After adjusting for stage and age at diagnosis, there was a trend in death rate reduction of 29% for those receiving chemotherapy compared with radiotherapy (HR, 0.712; 95% CI, 0.484–1.048; $p = 0.085$; 2-tail test). Of interest, those patients who received adjuvant radiotherapy had more late complications, mainly gastrointestinal, than those having cytotoxic therapy ($p < 0.001$). In addition, 2 patients undergoing radiotherapy died as a direct result of radiation-induced hepatitis (198).

A recent retrospective single institutional study from a major academic medical center attempted to further verify the results of GOG 150 by evaluating 49 patients with optimally debulked stage I–IV uterine CS who received either adjuvant radiotherapy alone (pelvic or whole abdominal irradiation ± vaginal brachytherapy)

Table 23.13 Patterns of Failure for Uterine Carcinosarcomas

Sites of Recurrence ^a	WAI (n = 105), Number of Cases	Chemotherapy (n = 101), Number of Cases

^aSome patients had multiple sites of relapse.

Modified from Wolfson AH, Brady MF, Rocereto T, et al. A Gynecologic Oncology Group randomized phase III trial of whole abdominal irradiation (WAI) vs. cisplatin-ifosfamide and mesna (CIM) as postsurgical therapy in stage I–IV carcinosarcoma (CS) of the uterus. *Gynecol Oncol*. 2007;107:177–185, with permission.

or predominantly paclitaxel/carboplatin chemotherapy (± whole abdominal or pelvic irradiation ± vaginal brachytherapy). Although not statistically significant due to small sample size, this latter report did show a reduction in upper abdominal relapses (24% versus 35%) and extravaginal/pelvic failures (45% versus 91%) in the group receiving combined modality adjuvant therapy versus the cohort receiving adjuvant radiation therapy alone, respectively (199).

Results from other retrospective series that focused solely on uterine CS are inconsistent with respect to the impact of adjuvant therapy on outcome with some demonstrating no benefit for postoperative radiotherapy (169,189,191,192,194), while others have shown a significant impact of pelvic PORT on survival for patients with carcinosarcomas (186,188,193,195). One of these above studies involved a review of the nonrandomized SEER database of 2,461 women with carcinosarcomas from 1973 to 2003 (195). In this data set, 890 patients received adjuvant radiotherapy. The overall 5-year survivals of those receiving radiotherapy versus no irradiation were 41.5% and 33.2%, respectively ($p < 0.001$). Furthermore, a significant improvement in survival in this study was observed for all stages of disease, including stage IV.

Finally, there have been several published retrospective reports suggesting that combined adjuvant radiotherapy and chemotherapy may impart even longer survival, especially in stage I and II disease (187,190,200). Nevertheless, the role of adjuvant radiotherapy for the management of patients with uterine carcinosarcomas continues to remain inconclusive. Since there were more vaginal failures in the chemotherapy arm of GOG protocol 150 and other sites of relapse were similar or less common in frequency (abdominal recurrences) than those in the radiotherapy arm, then perhaps postoperative vaginal brachytherapy (either high- or low-dose rate) with chemotherapy (of greater than three cycles) should be considered for any patient having optimally debulked carcinosarcomas in future trials.

Uterine Leiomyosarcomas

There are no existing randomized phase III trials that demonstrate any impact of adjuvant radiation therapy on LR relapses or survival in this patient population. There still remains a paucity of information that specifies between upper abdominal and extra-abdominal distant sites of tumor involvement. The respective pelvic/extrapelvic percentages were 18.5% (22 out of 119)/41.2% (49 out of 119) for nonirradiated and 12.9%

(8 out of 62)/43.5% (27 out of 62) for patients treated with postoperative radiotherapy (152,155,201). It does not appear that postoperative radiotherapy has any significant effect on reducing recurrences for patients with uterine leiomyosarcoma. However, 2 series combined to yield an 11.1% (4 out of 36) pelvic relapse rate with radiation versus 61.1% (22 out of 36) without the implementation of adjuvant radiation therapy (152,155). The major problem is that the majority of these patients have distant extra-abdominal metastases, such as the lung, despite having local control. There is an impending need in developing more effective systemic therapies to improve patient outcome (152,155).

A retrospective study from a single institution performed a case-control study of patients with uterine leiomyosarcomas; this study “showed a trend toward improved survival in the 31 cases with adjuvant pelvic irradiation compared with the controls who did not receive adjuvant radiation therapy” (27). Another more recent retrospective study of 143 patients with surgical stage I–IV uterine LMS from a consortium of institutions reported on 24 patients (17%) who received pelvic PORT and 63 (44%) who underwent adjuvant and/or palliative chemotherapy. This latter study found that the pelvic relapse rate was significantly reduced ($p = 0.02$) for patients undergoing radiotherapy (18%) versus those who did not have radiation therapy (49%). Although not maintained at 90 months of follow-up, this study also showed that the 5-year survival of the patients receiving adjuvant radiation (70%) was greater than those not having radiotherapy (35%) (202). The role of adjuvant radiotherapy in the management of patients with uterine LMS remains undefined.

Endometrial Stromal Sarcomas

There have been no randomized phase III trials that have been able to show any significant impact of adjuvant radiotherapy on outcome for patients with uterine EES. This class of endometrial sarcoma can be subdivided into either a low-grade category (ESS) or a high-grade sarcoma now termed undifferentiated uterine sarcoma. Gadducci and colleagues reported no abdominal or distant recurrences independent of the administration of adjuvant irradiation for all stages of low-grade ESS (203). Yet, there was a 33.3% (6 out of 18) pelvic recurrence rate, of which the majority did not undergo any radiation therapy. This latter finding suggests that postoperative external pelvis radiotherapy should at least be considered for the subset of patients with low-grade ESS.

One retrospective report reviewed 28 patients with ESSs of which 19 were low-grade and 9 were high-grade (204). Fifty percent of the patients in this series underwent adjuvant pelvic radiotherapy with no difference in the survival of the patients. In addition, almost 30% of those receiving adjuvant radiotherapy relapsed within the treatment field. Regarding undifferentiated endometrial sarcomas, another study documented multiple sites of recurrence, including abdominal (34.8% [11 out of 32]), distant (34.8% [11 out of 32]), and pelvic (40.6% [13 out of 32]) sites of relapse (205). However, a more recent small series of 13 patients with all stages of uterine EES showed that the 10 patient undergoing pelvic PORT (+/- vaginal boost) had an 89% LR control versus 50% LR control for the 3 not receiving any radiotherapy (206). Thus, the role of radiotherapy for patients with uterine EES remains uncertain.

CHEMOTHERAPY

Uterine sarcomas, although far less common than endometrial carcinomas, exhibit 2 features that would suggest a need

for systemic therapy: a recurrence rate of at least 50%, even in early-stage disease, and a high propensity for distant failure. The comparatively low incidence of uterine sarcomas has made randomized, controlled trials difficult. Despite this, cooperative group studies have provided data from phase II and III trials for the rational selection of systemic chemotherapy.

Crucial to the understanding of the use of chemotherapy in uterine sarcomas is the observation that these neoplasms are heterogeneous. Uterine carcinosarcomas (malignant mixed müllerian tumors) and leiomyosarcomas constitute 90% of cases entered into clinical trials. These 2 histologic subtypes are usually the only uterine sarcomas with sufficient numbers to permit meaningful phase III studies; however, as these 2 histologic subtypes appear to respond differently to chemotherapy, they should be studied separately.

Limited Disease

Uterine sarcoma has a high rate of distant metastases even in the absence of intraperitoneal or lymph node metastases. It has been concluded that this is due to the high rate of hematogenous and lymphatic dissemination (207). Therefore, the role of adjuvant systemic chemotherapy is under investigation in patients with apparently limited disease that has been fully surgically resected. A meta-analysis of almost 2,000 patients with localized resectable soft-tissue sarcomas (including uterine sarcomas) treated on small randomized trials of adjuvant anthracycline-based chemotherapy showed improved outcomes with chemotherapy compared to local treatment alone. There was an absolute risk reduction in recurrence of 12% and in death of 11% associated with doxorubicin-based chemotherapy combined with ifosfamide (208). Application of these data to uterine sarcoma is mired by the range of tumor sites included in the meta-analysis and the heterogeneity of sarcoma subtypes.

The largest randomized trial, to date, of adjuvant chemotherapy versus no further therapy in patients with uterine sarcoma did not segregate different histologic subtypes. Although the recurrence rate and median survival of patients treated with doxorubicin compared to no therapy were 41% versus 53% and 73 months versus 55 months, respectively, this phase III GOG trial of 156 evaluable patients concluded that there was no significant difference (183). Adjuvant pelvic radiotherapy was optional and not balanced between the arms. The fact that there was not a protocol-specified schedule of imaging for recurrence may have also affected the results. As with advanced disease, more recent trials have segregated the histologic subtypes. Previous studies reported that an effective adjuvant chemotherapy regimen was a combination of cyclophosphamide, vincristine, doxorubicin, and dacarbazine (DTIC); it yielded a 68% to 89% 5-year survival in stage I uterine sarcomas (209–212).

Uterine Carcinosarcoma

A nonrandomized study using adjuvant combination chemotherapy of etoposide, cisplatin, and doxorubicin demonstrated a 2-year survival of 92% in 23 patients with surgical stage I and stage II uterine carcinosarcoma. The fact that 7 patients also received radiation therapy makes interpretation of the results difficult (213). A pilot study concluded that multimodality treatment consisting of chemotherapy with epirubicin and cisplatin as well as radiation resulted in a 74% OS at a median follow-up of 55 months in 38 patients with surgical stages I and II uterine carcinosarcoma (200). However, the high dropout made the conclusion of multimodality treatment controversial. A phase III GOG study by Sutton et al. of 65 patients with completely resected stage I and II uterine carcinosarcoma who were treated with adjuvant ifosfamide and cisplatin reported 2- and 5-year survivals of 82% and 62%, respectively (214). Since more than

half of the recurrences involved the pelvis, the study suggested that a combined sequential approach with chemotherapy and radiotherapy might be beneficial for this group of patients. This would need to be verified in a randomized phase III study.

GOG 150, a phase III randomized study of patients with stage I–IV uterine carcinosarcoma (44% with stage I or II) who had undergone maximal resection of all gross disease compared whole abdominal radiation with three cycles of cisplatin and ifosfamide as adjuvant therapy. Although, not found to be statistically significant, there was a trend toward improved outcome in the chemotherapy group with recurrence and estimated death rates 21% and 29% lower, respectively, compared to the radiotherapy group (198).

Uterine Leiomyosarcoma

The role of adjuvant chemotherapy following complete resection of early stage uterine leiomyosarcoma is still under investigation but preliminary results of adjuvant systemic chemotherapy are promising. Two factors continue to limit the study of adjuvant therapy in patients with uterine leiomyosarcomas: the relatively low frequency of the disease, which makes it difficult to complete randomized trials in a reasonable period of time, and the lack of highly active agents.

The demonstrated activity of gemcitabine plus docetaxel in metastatic uterine leiomyosarcoma led to investigation of this combination in the adjuvant setting (215,216). A phase II, single-institution trial, of four cycles of fixed-dose-rate gemcitabine and docetaxel following complete resection of stage I–IV disease was performed (217). Among the 18 patients with early-stage disease, 59% remained disease-free at 2 years and the median OS had not been reached at the 5-year follow-up. The Sarcoma Alliance for Research through Collaboration (218) subsequently conducted a phase II, multicenter study of four cycles of adjuvant fixed-dose-rate gemcitabine docetaxel followed by 4 cycles of doxorubicin in 47 patients with uterus-limited leiomyosarcoma (219). Although 78% of the patients remained progression-free at 2 years, this dropped to 50% at the 3-year follow-up (220). Of note, in this study, age, menopausal status, hormone receptor status, grade, mitotic rate, or FIGO stage were not significantly associated with PFS. A proposed phase III multicenter randomized trial (GOG 277) will compare gemcitabine and docetaxel followed by doxorubicin to the current standard approach of observation, in order to determine if adjuvant chemotherapy improves outcomes for patients with uterus-limited high-grade leiomyosarcoma (221).

Low-Grade Endometrial Stromal Sarcomas

There are no data to support the use of adjuvant chemotherapy in patients who had complete resection of low-grade ESS confined to the uterus. The standard approach in this setting is observation alone. The role of adjuvant hormonal therapy in these patients has not been evaluated prospectively. Given the hormone-sensitive nature of these tumors, it is felt that estrogen replacement therapy may be detrimental in patients with low-grade ESS (222).

Adenosarcomas

Owing to the rarity of these tumors, there are no prospective data on the role of adjuvant systemic therapy for patients with completely resected adenosarcoma. Patients without “sarcomatous overgrowth” are often treated similarly to patients with ESS. The presence of “sarcomatous overgrowth” is associated with an increased propensity for disease spread and recurrence (144,223). Management for patients with “sarcomatous overgrowth” is often extrapolated from high-grade soft-tissue

sarcoma data. Patients should be encouraged to participate in clinical trials for soft-tissue sarcomas.

Advanced and Recurrent Disease

Neoadjuvant Chemotherapy

There have been no prospective studies evaluating the role of neoadjuvant chemotherapy in uterine sarcomas to date. The theoretical appeal of neoadjuvant therapy would be to not only potentially facilitate improved surgical outcomes through tumor shrinkage but also to permit an *in vivo* assessment of chemosensitivity to first-line drug therapy. The role of PET as an intermediate endpoint biomarker to assess treatment response early in patients with soft-tissue sarcomas undergoing neoadjuvant chemotherapy is under investigation (224).

Chemotherapy for Advanced/Recurrent Disease

Leiomyosarcomas

Numerous single agents have been, and continue to be, tested in patients with leiomyosarcomas (Table 23.14), but, unfortunately, results have been unimpressive (225–249). Doxorubicin and ifosfamide are the most active agents investigated as primary single-agent chemotherapy in recurrent and advanced uterine leiomyosarcomas. In 1983, the GOG demonstrated 7 responses among 28 patients (25%) treated with doxorubicin every 3 weeks as a single agent (231). This has been considered to be the most active single agent. The GOG has subsequently reported that treatment with liposomal doxorubicin yielded 1 complete (3.2%) and 4 partial (13%) responses and no advantage over historical results with doxorubicin (225). However, given the lower risk for cardiotoxicity, liposomal doxorubicin may remain a consideration for certain patients in whom doxorubicin therapy is precluded. The GOG demonstrated that ifosfamide had moderate activity, with 6 partial responses among 35 patients (17%) (228).

As in other types of soft-tissue sarcoma, gemcitabine has demonstrated activity with 1 (2.3%) complete response and 8 (18%) partial responses in persistent or recurrent uterine leiomyosarcomas (235). The median duration of response was only 4.8 months. In a small phase II study of temozolomide in advanced soft-tissue sarcoma, a partial response was seen in 2 (18%) of 11 patients with leiomyosarcoma (249). Limited activity was seen with single-agent paclitaxel, which was associated with a 9% overall response in 33 patients (227). Intravenous single-agent etoposide was shown to have an overall response of 11% in 28 patients (244), whereas prolonged oral etoposide had an overall response of 6.9% among 29 patients (243). However, no complete or partial responses were observed in another GOG phase II study with single-agent intravenous etoposide 100 mg/m² daily for 3 days every 3 weeks (229). Topotecan was tested in 36 patients with complete response in 1 (3%), partial response in 3 (8%), stable disease in 12 (33%), and increasing tumor in 20 (56%) (226).

A phase II study of trabectedin using a 24-hour infusion schedule in 20 chemotherapy naïve patients with advanced or recurrent uterine leiomyosarcoma demonstrated a 10% partial response rate with 50% of treated patients remaining progression-free for at least 6 months (250). Results of a randomized phase III study of trabectedin versus dacarbazine in patients with advanced leiomyosarcoma are awaited (NCT01343277). Trabectedin, although approved in Europe for the treatment of soft tissue sarcomas, is not approved in the U.S. thus far.

A small phase II trial of vinorelbine in patients who had failed prior doxorubicin-based chemotherapy demonstrated a

single partial response in 1 (6%) of 16 patients with leiomyosarcoma (248). Single-agent cisplatin also had a poor overall response of 3% to 5% in phase II trials (230,247). The antifolate compound trimetrexate was used in a small study reported in 2002, which was associated with an overall response of 4.3% in 28 patients who had received prior treatment (242). Mitoxantrone (246), diaziquone (234), amonafide (245), aminothiadiazo (233), and piperazinedione (232) were inactive as single agents. In a phase II trial comparing doxorubicin and docetaxel in advanced soft-tissue sarcoma, no objective responses were seen in the docetaxel group (251). Eribulin has also shown some promise in leiomyosarcoma (252). Newer agents such as the epothilone, ixabepilone, are currently being evaluated in phase II studies (NCT01220609).

Combination chemotherapy yields greater response rates (Table 23.14) (14,215,216,231,253-260). In 1983, the GOG demonstrated that the combination of doxorubicin and dacarbazine resulted in an overall response rate of 30%. Two years later, the same group demonstrated a 19% response rate using the combination of doxorubicin and cyclophosphamide (259). Both of the phase III trials were too small to make any definite conclusions. However, as mentioned, the trials did serve the purpose of allowing researchers to observe that leiomyosarcomas had a different chemotherapeutic response profile compared to uterine carcinosarcomas, resulting in the separation of the 2 different histologic entities in subsequent trials.

In 1996, the same group demonstrated an 18% overall response with a combination of dacarbazine, etoposide, and hydroxyurea (256). In the same year, using a combination of ifosfamide and doxorubicin, the GOG demonstrated an overall response of 30% in patients with advanced leiomyosarcoma with no history of prior treatment (257). A later study from the GOG showed that the use of mitomycin, doxorubicin, and cisplatin produced an overall response rate of 23% in 35 patients. Pulmonary toxicity was appreciable, however (255). Based on this study, the GOG conducted a phase II study with dacarbazine, doxorubicin, mitomycin, and cisplatin (DAMP), which produced a 28% response rate, but the complexity and toxicity of the regimen precluded further investigation, and the study was closed after the first stage of accrual (253).

Fixed dose-rate gemcitabine plus docetaxel was proven highly active and tolerable (40% overall response rate) in treated and untreated patients with uterine leiomyosarcomas (261). As initial therapy for metastatic uterine leiomyosarcoma this combination achieved a 36% response rate (2 complete and 13 partial responses) among 42 patients (216). The response rate for the doublet was 27% in the second-line setting, with a median PFS of greater than 5.6 months.

A phase II trial of fixed-dose rate gemcitabine and vinorelbine in patients with advanced soft-tissue sarcoma yielded a response rate of 22% in the nine uterine leiomyosarcoma patients but did not impart any advantage over historical results with single-agent gemcitabine (260). A combination of temozolomide and thalidomide in advanced leiomyosarcoma yielded a single (4%) response rate (262).

The effort in leiomyosarcomas continues to focus on the identification of active drugs and combinations in phase II trials. Given the paucity of survival data available from the randomized trials to compare various chemotherapy regimens, a pooled analysis of phase II studies was undertaken to compare the difference of response rate between single-agent and combination therapy. It showed that patients who received first- or second-line chemotherapy for the treatment of metastatic leiomyosarcoma had a higher response rate with combination chemotherapy than with single-agent chemotherapy (263). However, current phase III randomized clinical trials are only suggestive of the role of combination chemotherapy in advanced or recurrent uterine leiomyosarcomas.

Carcinosarcomas

Several drugs have been studied in this group of tumors as single agents (Table 23.15) (231,246,253,264-277). However, only 3 drugs have demonstrated clear-cut activity: ifosfamide, cisplatin, and paclitaxel (264-267,271,276,277). In a 5-day schedule, ifosfamide produced 25 complete and 12 partial responses (overall response of 36%) among 102 patients with no prior chemotherapy (185). In patients with prior chemotherapy, cisplatin produced an 18% response in 28 patients (276). A repeat trial in patients with no prior chemotherapy documented essentially the same response rate of 19% among a larger group of patients (264). Both trials used cisplatin at 50 mg/m² every 3 weeks. Investigators at the M. D. Anderson Cancer Center employed a higher dose ranging from 75 mg/m² to 100 mg/m² every 3 weeks. Only 12 patients with measurable disease were entered into the trial, but 1 complete and 4 partial responses were observed (overall responses, 42%) (277). The lack of randomization and the small number of cases in this trial preclude conclusions about the merits of the higher dose. Paclitaxel as a single agent was associated with a response rate of 21% in a group of 33 patients with uterine sarcoma who had prior chemotherapy, with an 8.2% response rate in patients who failed appropriate local therapy (271).

Doxorubicin, generally regarded as the most active agent in soft-tissue sarcomas, unfortunately demonstrated inconsistent activity in three trials of patients with uterine carcinosarcoma. The first 2 studies constituted 1 arm of each of 2 randomized trials. In the first, four responses among 41 patients (10%) with uterine carcinosarcomas (231) were observed. The second demonstrated a 19% response rate utilizing a dose of 60 mg/m² every 3 weeks in recurrent or advanced uterine sarcomas (259). The third, which employed a range of doses from 50 mg/m² to 90 mg/m² every 3 weeks, resulted in no response among the 9 patients with measurable disease (268). Topotecan 1.5 mg/m² daily for 5 days had unimpressive activity (10% response rate) in patients with advanced or recurrent uterine carcinosarcomas previously treated with chemotherapy (269). Demonstrating negligible activity in phase II studies were etoposide (275), mitoxantrone (246), piperazinedione (237), diaziquone (274), amonafide (272), trimetrexate (270), and aminothiadiazo (273).

In general, combination chemotherapy regimens usually result in a higher response rate than single-agent regimens. However, not all combination regimens have had an impact upon survival. This is clearly seen in the treatment of uterine carcinosarcomas. There have been numerous reports of combination chemotherapy for uterine carcinosarcomas (Table 23.15) (231,259,266,270,278-282). A combination of cyclophosphamide, vincristine, doxorubicin, and DTIC had a reported 23% overall response rate (281). A combination of etoposide, hydroxyurea, and DTIC resulted in a response of 15% in 32 patients (279). Subsequently, the EORTC reported a trial based upon 48 patients with unresectable or recurrent carcinosarcoma who were treated with a combination of cisplatin, doxorubicin, and ifosfamide. The overall response rate was an impressive 56%. Unfortunately, this regimen was also associated with a high incidence of nephrologic and hematologic toxicities (282). A phase II study of carboplatin and paclitaxel as first-line chemotherapy for women with advanced uterine carcinosarcoma reported an overall response rate of 54% with a favorable toxicity profile (283).

The first randomized study in 1983 by the GOG, which combined uterine carcinosarcoma with other sarcomas, resulted in patient numbers being too small for subset analysis (231). Nonetheless, combining doxorubicin and DTIC resulted in an overall response of 23% and a trend toward greater response as compared to single-agent doxorubicin (10%). A significant improvement in progression-free and OS could not be demonstrated, but

^bFemale genital tract.

2 conclusions could be drawn from this trial. The first was the fact that a greater response to chemotherapy was significantly associated with an increase in OS and the disease-free survival. The second observation was that uterine carcinosarcomas had a different response profile compared to leiomyosarcomas. Two years later, the GOG compared cyclophosphamide plus doxorubicin to single-agent doxorubicin. A response of 25% was observed in carcinosarcomas; again, however, numbers were inadequate to show any significant benefit compared with single-agent doxorubicin. The trial was also closed early because of failure to reach statistical significance (259).

With the recognition of the difference in response to therapy between carcinosarcomas and leiomyosarcomas, randomized trials began to regard each of the 2 major histologic subtypes as separate patient populations. Unfortunately, this increased the time necessary to complete clinical trials. Nonetheless, a large randomized trial was performed and reported in 2000. The GOG evaluated the addition of cisplatin to ifosfamide in 194 eligible patients and found that this improved the overall response rate from 36% to 54% and prolonged the median progression-free interval by an absolute 2 months. However, this advantage was not associated with a significant OS gain and 6 treatment-related deaths occurred (266).

Based upon the finding of moderate activity (18% response rate) of paclitaxel for this disease (271), the GOG carried out a phase III trial of 3-day ifosfamide with or without paclitaxel in advanced uterine carcinosarcoma. The group found that the addition of paclitaxel produced a 45% response rate compared with 29% in the ifosfamide single-agent arm with OS significantly improved. There was a significant decrease in the hazard of death and progression but more sensory neuropathy, as expected (265). A recent meta-analysis supports the use of combination chemotherapy in advanced or recurrent uterine carcinosarcomas with a reduction in the risk of death and disease progression compared to single-agent therapy (284). In order to determine the best first-line chemotherapy doublet, the

GOG are now conducting a noninferiority phase III trial, GOG 261, comparing paclitaxel with carboplatin and paclitaxel with ifosfamide in patients with uterine or ovarian carcinosarcoma (NCT00954174).

Data regarding second-line chemotherapy doublets is limited. A phase II trial of weekly gemcitabine and docetaxel in recurrent uterine carcinosarcoma was associated with an 8.3% overall response rate with a median PFS of only 1.8 months (285). Combination regimens that result in significant improvements in survival are still needed (Table 23.16).

Endometrial Stromal Sarcoma

In recurrent ESS, reports support hormonal therapy for patients with low-grade subgroup (13), and chemotherapy for high-grade tumors (286). Current definitions do not include high-grade lesions as a component of ESS. In a retrospective review of 74 patients with low-grade stromal sarcoma, none of the 10 patients who received chemotherapy had a response compared to 27% of patients who were treated with hormonal therapy (13). Randomized phase III trials with stromal sarcomas are limited due to the rarity of this disease. Two randomized trials compared single-agent and combination chemotherapy in advanced uterine sarcoma but did not report the response rate of stromal sarcomas separately. The GOG reported a phase II study of ifosfamide treatment in 21 cases with recurrent or metastatic ESSs. Three patients experienced complete response and four had partial responses, for an overall response of 33.3% (287). Another noncontrolled study observed a 50% response rate to doxorubicin therapy in ten patients with recurrent ESSs (288). Many other literatures are case reports and retrospective studies with a small number of cases. Published chemotherapy regimens include carboplatin and paclitaxel (289); doxorubicin, cisplatin, and ifosfamide (290); doxorubicin and ifosfamide (291); doxorubicin, vincristine, and cyclophosphamide (292); and prolonged oral etoposide (293).

^aUterine sarcoma.

^bFemale genital tract.

High-Grade Undifferentiated Endometrial Sarcoma

There are no prospective trials of chemotherapy specifically for high-grade undifferentiated endometrial sarcoma. Case reports of responses to ifosfamide and doxorubicin-based chemotherapy regimens have been documented in the literature (294,295). A phase II trial of first-line chemotherapy for recurrent of metastatic ESS reported a 33% response rate but did not segregate high-versus low-grade tumors (296). Participation in clinical trials for soft tissue sarcomas should be encouraged due to the paucity of data to guide systemic treatment.

PEComa

There are no prospective data on systemic chemotherapy for PEComa. A case report of a 9-year-old girl with uterine PEComa reported radiographic response following 2 cycles of neoadjuvant vincristine, ifosfamide, and doxorubicin, but analysis of the surgical specimen did not demonstrate any tumor response. Case reports of tamoxifen or anthracycline-based chemotherapy following surgical resection of gynecologic PEComas did not suggest any benefit from adjuvant therapy (176). In the metastatic or recurrent setting chemotherapy again did not appear to be effective (297). Sirolimus, a mammalian target of rapamycin (mTOR) inhibitor, which has activity in nonuterine PEComas, was not associated with responses in patients with uterine PEComas (298). Participation in clinical trials for soft-tissue sarcomas should be encouraged for these patients.

Rhabdomyosarcoma

Due to the rarity of uterine rhabdomyosarcoma, there are no prospective data to guide optimal therapy (177). Complete responses have been reported with neoadjuvant ifosfamide, vincristine, and actinomycin D combination chemotherapy in case series of pediatric patients with rhabdomyosarcoma of the genital tract (178).

Toxicity of Systemic Therapies

The most common toxicities of chemotherapy are hematologic and gastrointestinal toxicity. The grade 3–4 adverse effects of chemotherapy with overall response rate higher than 5% in leiomyosarcomas and carcinosarcomas are listed in Tables 23.17 and 23.18. Combination chemotherapy has a much higher incidence of grade 3–4 side effects compared with the single-agent regimen. The overall response rate of combination with ifosfamide plus cisplatin is 54%; however, the grade 3–4 of leukopenia is 97%, and 6 deaths occurred before the first dose reduction of ifosfamide (266). The more recent phase III trial with ifosfamide plus paclitaxel reported a 45% overall response rate with tolerable toxicities (265), which seems a relatively effective and safe regimen. Among other phase II trials of different chemotherapeutic regimens, liposomal doxorubicin, paclitaxel, doxorubicin, cisplatin, and etoposide plus cisplatin plus doxorubicin were reported to have less toxicity with moderate effect. Despite the routine use of growth factor support with gemcitabine and docetaxel, myelosuppression, in particular in previously treated patients, is still the predominant toxicity encountered with this combination (215,216). Lower limb edema is also more common in the second-line setting. Trabectedin is associated with fatigue, myelosuppression, transaminitis, and vomiting (299).

Newer agents such as palifosfamide-tris and eribulin may offer a more tolerable toxicity profile compared to the standard chemotherapy drugs. Palifosfamide-tris is a stabilized active metabolite of ifosfamide with less potential for bladder toxicity.

There is currently a phase III randomized study of doxorubicin plus palifosfamide/placebo as first-line chemotherapy for patients with metastatic soft-tissue sarcoma (NCT01168791). Another randomized ongoing phase III compares eribulin with dacarbazine in patients who have progressed within 6 months of standard chemotherapy (NCT01327885).

Hormonal Therapy

Although the role of hormonal therapy is clear in breast and endometrial cancers, it has not been extensively evaluated in mesenchymal uterine tumors. Few uterine sarcomas contain sufficient estrogen- or progesterone-receptor protein to influence therapy, the only exception being low-grade ESSs or stromal nodules. Estrogen and progesterone receptors were found in 55.5% and 55.8%, respectively, of samples from patients with various types of uterine sarcomas, but the median concentrations were substantially lower than those observed in breast or endometrial cancers. ESSs had higher receptor levels (300). Uniquely, low-grade ESSs are hormonally responsive in roughly two-thirds of cases, and long-term maintenance therapy should be beneficial. Several papers reported that long-term use of tamoxifen for the treatment of breast cancer was related to the development of uterine sarcoma (301,302). This is likely secondary to the stimulatory estrogenic effects of tamoxifen on the uterus. It is also, therefore, reasonable to avoid estrogen replacement therapy for these patients.

Endometrial Stromal Sarcoma

Progestins, gonadotropin-releasing hormone (GnRH) analogues (303), or aromatase inhibitors (286,304) have been used in the treatment of patients with advanced or recurrent ESSs, and they successfully gain long-term stability in case reports. A retrospective study of patients with low-grade ESS reported a response rate of 27% (5 complete and 3 partial responses), stable disease in 53% (16 patients), and a median time to progression of 24 months in the subgroup of patients who received hormonal therapy (13). The vast majority of these patients received megestrol acetate.

Lantta et al. (305) published 2 cases of extensive intraperitoneal low-grade ESS associated with high levels of progesterone receptors in complete remission with hormonal therapy. Three patients with high levels of progesterone receptors were reported by Baker et al. (306) to have partial responses or stabilization of disease on oral megestrol acetate. Piver et al. (307), in a collaborative survey of endolymphatic stromal myosis, recorded complete or partial responses to hormonal therapy in 6 of 13 patients (46%) treated with progestational agents. Scribner and Walker (308) reported a patient with an extensive ESS of the uterus whose tumor was reduced to resectable size by the administration of leuprolide acetate and megestrol acetate. Low-grade ESSs have also been reported to express *srp27*, an estrogen-induced 24-DK protein suggesting hormone responsiveness (309). Medroxyprogesterone acetate has induced major responses in pulmonary metastatic lesions from ESS (310,311). GnRH analogues were reported to control the progression of a recurrent low-grade ESS with moderate estrogen and progesterone receptor positivity (303). Medroxyprogesterone acetate and aromatase inhibitors, such as letrozole, were observed to be highly effective and have sustained progression control in 6 of 10 cases with low-grade stromal sarcoma (312). Spano et al. presented two cases of ESS with lung metastases treated with aminoglutethimide who achieved complete response and remained disease-free for 14 and 7 years, respectively (286). In a phase II trial of mifepristone, a selective progesterone receptor modulator, in recurrent, uterine cancer, no responses (0%) were seen in the 2 patients with low-grade ESS (313).

Other Uterine Sarcomas

There are anecdotal reports of responses to hormonal therapy in adenosarcomas and low-grade leiomyosarcomas (314). A retrospective study of an aromatase inhibitor in selected patients with advanced, predominantly low-volume disease, reported a partial response in 3 patients (9%). Patients whose tumors did not express estrogen or progesterone receptors did not derive any benefit from the aromatase inhibitor (315). The role of the aromatase inhibitor, letrozole, in advanced hormone receptor positive uterine leiomyosarcoma is being evaluated prospectively in an ongoing, open label phase II trial (NCT00856050). Another prospective study is comparing letrozole with observation for newly diagnosed uterine leiomyosarcoma (NCT00414076). One case of letrozole therapy in high-grade uterine carcinosarcoma with marked tumor control was reported, but the area has not been well studied (316).

Biologic Therapy

Since the high recurrence and poor response to radiotherapy and chemotherapy, biologic therapy may have more promise in the area of uterine sarcoma, as well as other types of soft-tissue sarcoma. The recent advances in the biology of uterine sarcoma related to probable treatment target have concentrated on tyrosine kinase receptors, vascular endothelial growth factor (VEGF), and the phosphatidyl 3-kinase (PI3K)/Akt pathway.

Since the discovery that high proto-oncogene *c-kit* expression in gastrointestinal stromal tumors (GISTs) may be amenable to control with tyrosine kinase inhibitors, such as imatinib mesylate and sunitinib, some interest has been focused upon uterine sarcomas (317). However, the expression of *c-kit* in the uterine sarcoma varies greatly in different studies (318–320). Given the great progress made in the GISTs with imatinib mesylate, a GOG phase II evaluation of this drug was conducted in previously treated patients with recurrent or persistent carcinosarcoma of the uterus (320). No activity was seen. The GOG investigated sunitinib maleate as a second- or third-line therapy for leiomyosarcoma of the uterus. The trial was reported as negative, with only 2 partial responses (9%) noted among the 23 patients (321).

Emoto et al. demonstrated inhibition of a VEGF-expressing malignant mixed tumor cell line by TNP-470, an angiogenesis inhibitor (322). Another angiogenesis inhibitor, thalidomide, did not demonstrate any activity in recurrent or persistent uterine carcinosarcoma (323) or uterine leiomyosarcoma (324). A phase II study of sorafenib, a small-molecule B-raf and VEGF receptor inhibitor, was also negative with only 1 (3%) partial response seen among the 37 patients with adult leiomyosarcoma (325). No responses were observed in a phase II trial of aflibercept in recurrent or metastatic gynecologic carcinosarcomas and uterine leiomyosarcoma (326).

A phase II study of pazopanib, an oral multitargeted kinase inhibitor, showed 1 partial response (2.4%) among the 41

patients in the leiomyosarcoma cohort (327). In the recently reported phase III trial of pazopanib versus placebo as second-line therapy for metastatic soft-tissue sarcoma (46% leiomyosarcoma), the response rate was 6% in the pazopanib group. There was a 3-month increase in PFS. Although this did not translate into a significant improvement in OS, pazopanib is now FDA-approved for patients with advanced soft-tissue sarcoma who have previously received chemotherapy (328). As there is a potential for life-threatening hepatotoxicity with this drug, patients should be carefully monitored for liver function. The results of a GOG phase II trial of pazopanib in previously treated uterine carcinosarcoma are awaited (NCT 01247571). There are also proposals to study this drug in combination with gemcitabine as second-line therapy for leiomyosarcoma (NCT01442662).

A phase II study of doxorubicin with bevacizumab in 17 chemotherapy-naïve patients with soft tissue sarcoma reported a lower than anticipated response rate of 12%, with significant cardiotoxicity ($\geq$ grade 2 in 35% of patients) (329). Among the 7 patients with uterine leiomyosarcoma, there were 2 (28%) partial responses. The GOG are currently conducting a phase III, placebo-controlled trial of gemcitabine and docetaxel with or without bevacizumab as first-line therapy for advanced or recurrent uterine leiomyosarcoma (NCT01012297).

Loss of PTEN function results in upregulation of the PI3K/Akt pathway and was shown to be associated with high-grade and recurrence of leiomyosarcoma (330). mTOR is a central regulator of this pathway. Ridaforolimus (formerly deforolimus), an mTOR inhibitor, did not show any responses in the 56 leiomyosarcomas patients but 36% had disease stabilization at 16 weeks (331). A phase III study of ridaforolimus as a maintenance strategy in metastatic sarcoma patients following benefit from chemotherapy reported a disappointing 3-week increase in PFS (332). Although there are published case reports of activity of sirolimus in nonuterine PEComas, this mTOR inhibitor does not appear to be active in uterine PEComas (298).

Advances in the understanding of the biology of uterine sarcomas may provide more treatment targets and make long-term control of the disease possible.

Systemic Therapy Summary

The current role of chemotherapy in the management of uterine sarcomas involves the treatment of patients with advanced or recurrent disease, and an emphasis on palliative intent. In leiomyosarcomas, the active drugs are doxorubicin, ifosfamide, gemcitabine, and docetaxel. For uterine carcinosarcomas, the drugs of choice are ifosfamide, cisplatin/carboplatin, and paclitaxel. Hormonal therapy, including progestational agents, GnRH analogues, and aromatase inhibitors, has a role in the treatment of advanced or recurrent low-grade ESSs. The use of hormonal agents in the treatment of other histologic subtypes has not been well studied. Efforts to identify additional active agents continue.

EPIDEMIOLOGY AND RISK FACTORS

Established risk factors for ovarian cancer include a strong family history, early menarche, late menopause, increasing age, and nulliparity. The most important risk factor, after having a first-degree relative with the disease, is age. Women younger than 40 years without a positive family history rarely have ovarian cancer. Fifty percent of all cases of ovarian cancer in the United States occur in women over the age of 65. Older women have a much worse prognosis overall (Fig. 24.1) in part because they have an increased incidence of high-stage and high-grade disease at the time of diagnosis (Table 24.1) (1,2). However, in an analysis of the The Surveillance, Epidemiology, and End Results (SEER) database, age remained a poor prognostic factor even when results were adjusted for stage, grade, histologic cell type, race, and surgical treatment. The relative risks (RR) associated with endocrinologic factors are much smaller, though important, because they are potentially subject to modulation.

Epidemiology

Epithelial ovarian cancer is the leading cause of death from gynecologic cancer in the United States and Europe (excluding breast cancer). Data from the American Cancer Society suggested that 22,280 new cases of ovarian cancer and 15,500 deaths from ovarian cancer would be expected in the United States in 2012 (3). It has been estimated that, in the United States, 1 woman in 70 will develop ovarian cancer, and 1 woman in 100 will die of the disease. In Europe, the International Agency for Research on Cancer in Lyon estimated that in the 40 European reporting countries, there will be 66,734 new patients with ovarian cancer and 41,929 deaths (4). Both in the United States and in Europe, ovarian cancer is the fifth most common cause of cancer death. Estimates for global ovarian cancer burden, which include low malignant potential cancers (the U.S. and European numbers exclude it), are that 225,500 patients will develop epithelial ovarian cancer and about 140,200 will succumb to the disease.

Ovarian cancer rates vary between different countries and appear to be linked to socioeconomic status and reproductive patterns. North America and most of the industrialized countries of Europe have high incidence rates, while the disease is rare in Asia and Africa. The lowest rates of ovarian cancer are in Sub-Saharan Africa (Fig. 24.2). While the reason for this difference has not been elucidated, countries with a high incidence rate are generally characterized by smaller family sizes, high-fat diets, higher socioeconomic status, older age, and a predominantly Caucasian population. Once a woman moves from a country with a low incidence of ovarian cancer to one with a high incidence, her risk for the disease tends to approach that of the adopted country rather than the country of origin.

Weight/Body Mass Index

Many epidemiologic studies have reported that height and weight are relevant to a woman's risk of developing ovarian cancer, although the findings of these studies have been inconsistent. In a prospective cohort study that followed 495,477 women for 6 years, body mass index (BMI) and ovarian cancer mortality were significantly associated (Fig. 24.3). For women with a BMI of 35 to 39, the relative risk of developing ovarian cancer was 1.5 (CI, 1.1–2) while the relative risk of developing endometrial cancer was 6.3 (CI, 3.8–10.4). In 2012, a meta-analysis that summarized 47 studies involving 25,157 women with ovarian cancer and 81,311 women without the disease found a significant increase in relative risk (RR, 1.07) of ovarian cancer per 5-cm increase in height. The relative risk for ovarian cancer per 5 kg/m² increase in BMI was 1.1 in women who did not take hormone replacement therapy (HRT) but only 0.95 in women on HRT (6). The relationship between ovarian cancer risk and a high BMI at age 18 was stronger than the relationship between ovarian cancer risk and a high BMI occurring later in life (7). In summary, there is probably a small (1.3) but significant increase in the odds ratio for developing ovarian cancer if a woman's BMI is more than 30 (5,8). Given that the association of obesity and ovarian cancer is not strong, it is possible that it is caused by other confounding factors such as type 2 diabetes, high-fat diets, or factors that are currently unknown (9).

Reproductive Factors: Pregnancy and Breast Feeding

Early menarche and late menopause increase the risk of ovarian cancer, while increased parity, breastfeeding, and the use of oral contraceptives (OCP) reduce the risk. These findings suggest that the risk for ovarian cancer is linked to the number of ovulations that a woman experiences throughout her lifetime.

Several epidemiologic studies clearly show that pregnancy, breast-feeding, and OCP use are associated with a reduced risk of developing ovarian cancer (10–12). In addition, a number of case-control studies have shown that pregnancy lowers ovarian cancer risk and that the risk reduction is higher with each additional pregnancy. Interestingly, a pregnancy after age 35 is more protective against ovarian cancer than a pregnancy in a woman 25 years or younger (13).

In general, breast-feeding reduces the risk of ovarian cancer: Women who breast-feed for longer than 12 months have a substantial reduction in the risk of ovarian cancer, which is in addition to the risk reduction derived from childbirth (14). Breast-feeding probably reduces ovarian cancer incidence through several mechanisms, including suppression of ovulation, reduced serum concentrations of estradiol and LH, and elevated FSH levels.

Oral contraceptives

Women who use OCP for at least 5 years reduce their risk of ovarian cancer by an average of 50%, and the level of protection increases with duration of use (10) (Fig. 24.4). Therefore, protection against ovarian cancer is probably the most important noncontraceptive benefit of OCPs. A meta-analysis reanalyzing data from 45 epidemiologic studies, which included 23,257 women with ovarian cancer and 87,303 controls, showed that in high-income countries, the use of OCP reduced ovarian cancer incidence from 1.2 to 0.8 per 100 users and mortality from 0.7 to 0.5 (15). These data confirmed not only that women who use OCP are at reduced risk of ovarian cancer, but also that the protection continues for decades after OCPs are discontinued. Furthermore, the reduction in risk is greater with more prolonged use. However, OCP had little effect on risk for

mucinous tumors, which is consistent with a different biology of these tumors (16) and the current understanding that most are metastatic from the gastrointestinal tract.

The mechanisms underlying the profound and long-lasting protection against ovarian cancer provided by the OCPs are not well understood. The protective effects may be mediated by suppression of ovulation, reduction of gonadotropin levels, and/or induction of apoptosis (10). In view of the protective effects of parity and breast-feeding, however, the mechanism of protection might involve the reduced number of lifetime ovulatory cycles and its associated injury to the epithelial cells on the surface of the ovary. According to an older hypothesis (the “incessant ovulation” hypothesis) (17), ovarian cancer develops from an aberration in the repair process of the surface epithelium, which is ruptured and repaired during each ovulatory cycle. In support of this theory, it is well known that domestic

egg-laying hens, which are forced to ovulate incessantly, have a high incidence of lesions believed to be ovarian-derived tumors with peritoneal carcinomatosis (18, 19). Alternative hypotheses addressing how OCPs may reduce ovarian cancer incidence center around their ability to treat endometriosis and reduce the risk of acquiring pelvic inflammatory disease (PID) (20), 2 conditions known to be associated with ovarian cancer (see below). However, these hypothesis are at odds with an origin of ovarian cancer in the fallopian tube (21; see Pathology section).

A case-control study has shown that progestin-only contraceptive users have a reduced risk (0.39) for developing ovarian cancer (22, 23). Moreover, the increase in progestin levels seen during pregnancy suggests that the protective effect of pregnancy may involve progestins as well as the reduction in the number of lifetime ovulations. Recent studies in primates indicate that the progestin component of OCPs has a chemopreventive effect by inducing apoptosis of ovarian surface cells that have undergone genetic damage (24). This is supported by the finding that women who use a long acting progestin-only contraceptives (Depo-Medroxyprogesterone Acetate—Depo Provera), which does not completely suppress ovulation, experience a protective effect similar to that observed with OCPs, which completely suppress ovulation (10).

Hormone Replacement Therapy

Currently, the primary indications for the prescription of HRT are severe postmenopausal symptoms and osteoporosis. Several prospective cohort studies (12, 25–28) examined how postmenopausal estrogen or estrogen/progestin HRT relates to the risk of developing ovarian cancer. Using data from the Breast Cancer Detection Demonstration Project, which is a cohort study of over 44,000 postmenopausal women, Lacey and colleagues found that use of estrogen-only HRT increased ovarian cancer RR by 1.6 (CI, 1.2–2), while the RR for women using an estrogen/progestin combination was not significantly increased (RR, 1.1; 0.64–1.7) (11). In a prospective, double-blind study, the Women's Health Initiative (WHI), over 8,000 women who had not had a hysterectomy were randomized to either placebo or 0.625 mg conjugated equine estrogen with 2.5 mg medroxyprogesterone acetate (25). After an average of 5.6 years of follow-up, 20 women in the estrogen/progestin group were diagnosed with an invasive ovarian cancer versus 12 in the placebo group, which is not a significant difference (HR: 1.64; 0.78–3.45). There was no difference in the histologic subtype of ovarian cancers between the 2 groups. While the authors found the increase worrisome, they also pointed out that, because the absolute number of women who developed ovarian cancer was small, the trial had limited precision in this regard, and risk of ovarian cancer should therefore “not have an appreciable influence on most women's decision making when seeking relief for moderate to severe vasomotor symptoms” (25). The observational “Million Women Study” (26), confirmed an increased risk with estrogen-only HRT (RR, 1.49; 1.2–1.81) and showed a lower risk with estrogen/progestin combination therapy (RR, 1.15; 1–1.33). This study also reviewed the cumulative incidence of gynecologic cancers, including ovarian, endometrial, and breast cancer in women taking HRT. The gynecologic cancer incidence per 1,000 women increased from 19 per 1000 in “never-users” to 26 per 1000 in current users of estrogen only, and to 35 per 1000 in current users of estrogen/progestin combinations (Fig. 24.5). The strength of this study, which followed nearly 1 million women, was that the results were adjusted for age at menopause, OCP use, BMI, smoking, and physical activity. HRT was found to be unrelated to the risk of mucinous ovarian cancer.

FIGURE 24.5. Standardized incidence rates (95% CI) for ovarian, endometrial and breast cancer per 1000 women in the study cohort over a 5-year period, for current users of various types of HRT and for never users*

*Incidence rates are standardized by age, region of residence, socioeconomic status, time since menopause, parity, use of oral contraceptives, BMI and alcohol consumption. Rates apply to women with a uterus and ovaries.

In conclusion, a review of the major studies suggests a 30% to 58% increase in ovarian cancer risk in women who take HRT (12, 25–28). The risk is certainly increased in women taking estrogen-only HRT independent of whether they had a previous hysterectomy (11). Regular use of vaginal and transdermal estrogen also carries a slightly increased risk of ovarian cancer (26, 28). Most of the studies found that estrogen-progestin HRT and estrogen-only HRT are associated with essentially equal risk, calling a possible protective effect of progestins into question (12, 26, 28). However, one large study found no evidence that estrogen/progestin combinations increase the incidence of ovarian cancer (11). The risk of ovarian cancer was found to increase with duration of HRT exposure, and the largest risk was seen among women who used HRT for over 20 years. Most studies show that a treatment duration of less than 5 years carries no statistically increased ovarian cancer risk (26, 27), although one study did find that even a short duration of use increases risk (28). The negative impact of HRT on ovarian cancer risk is reversible after 2 years, when it approaches the risk observed in never-users (26, 28). This suggests that HRT has a direct growth-promoting effect on steroid receptors expressed on ovarian cancer cells (16,22). In contrast, the positive, risk-reducing effect of OCPs is maintained even 2 decades after the pill is discontinued.

The risk of excess ovarian cancer with HRT is relatively small, and could be represented as one extraovarian cancer for every 8,300 women who take HRT (28). This should not be the deciding factor in clinical decisions regarding HRT use. Current clinical practice is to prescribe HRT to patients with severe postmenopausal symptoms and to administer it at the lowest effective dose for a limited period of time (less than 5 years) (26, 27). Short-duration, low-dose use of HRT for menopausal symptom management seems to have an acceptable risk-benefit ratio for some women.

Surgery: Tubal Interruption and Hysterectomy

In general, studies have confirmed that both tubal interruption and hysterectomy at least partially protect against the development of ovarian cancer. The four most common surgical sterilization methods, tubal ligation, thermal injury, rings, and clips are probably equally effective in reducing risk. A large prospective cohort study, the Nurses Health study (29), confirmed smaller case-control studies and showed a RR of 0.33 (CI, 0.16–0.64) of developing ovarian cancer in women who had a tubal ligation compared to those who did not. The same study reported a weak inverse relationship between hysterectomy and ovarian cancer (RR, 0.67; CI, 0.45–1). The effect of hysterectomy was greater when the surgery was performed at an earlier age.

Since tubal ligation could serve as a form of secondary prevention of ovarian cancer for women at risk, a retrospective case-control study evaluated the effect of tubal ligation in patients with *BRCA1* mutations (30). In this high-risk group, women who had undergone a tubal ligation had a considerably reduced risk of developing ovarian cancer when compared to women who had not (OR, 0.39; CI, 0.22–0.7). Women who both had a tubal ligation and had used OCP in the past had an even lower odds ratio of developing ovarian cancer (OR, 0.28; CI, 0.15–0.52). Possible explanations for the protective effect of tubal interruption against ovarian cancer include an impaired blood supply to the ovaries/distal tubes through the superior branch of the uterine artery leading in most women to earlier menopause (and fewer lifetime ovulations) and the possibility that occluding the tube blocks the upward flow of carcinogens from the uterus and reduces pelvic infection rates.

Inflammation: Pelvic Inflammatory Disease and Endometriosis

Pelvic Inflammatory Disease (PID) is a generalized infection of the female genital tract. Several small case-control studies had suggested that PID is associated with ovarian cancer. However, this association only gained wide acceptance with the publication of a large study (31) comparing the ovarian cancer incidence of 68,000 women who had experienced PID versus 136,000 who had not. In this well-designed study, the hazard ratio for ovarian cancer in patients with a history of PID (adjusted appropriately for confounding factors) was twice as high (HR 1.92) as that of controls, and was even higher (HR 2.46) in women who had at least 5 episodes of PID. Such indications of a dose-response effect always add credibility to epidemiologic findings (32).

Endometriosis, characterized by the ectopic growth of endometrial glands in the ovary and the abdominal cavity, affects 10% of women of reproductive age. In smaller case-control studies, a history of endometriosis has been consistently shown to be associated with clear cell and endometrioid ovarian carcinoma with an odds ratio of approximately 2. In many endometrioid and clear cell ovarian cancers, endometriosis is detected histologically adjacent to the carcinoma. Combining data from 13 ovarian cancer case-control studies (7,900 patients with ovarian cancer), the Ovarian Cancer Association Consortium (OCAC) published a definitive report that self-reported endometriosis increased the risk of clear cell (OR, 3.05; CI, 2.4–3.8) and endometrioid ovarian cancer (OR, 2.04; CI, 1.7–2.5) (33). In this report endometriosis was also associated, for the first time, with low-grade serous cancers (OR, 2.11; CI, 1.4–3.2), suggesting that these cancers, which are generally believed to arise from serous borderline tumors, can also arise from endometriotic implants.

There are 2 pathologic subtypes of endometriosis: displaced benign ectopic endometrial glands and atypical endometriosis. Given the high prevalence of endometriosis, it is likely that “benign” endometriosis acts through the creation of a

microenvironment of chronic inflammation and is only one of several factors that can spur the development of clear cell and endometrioid cancers. In contrast, the endometriosis with cytological atypia and complex hyperplasia (“atypical endometriosis”) present in 2% to 3% of all patients who undergo surgery for endometriosis is most likely a direct precursor for type I/low-grade ovarian cancers (34,35). This hypothesis was supported by a recent study in which *ARID1A* gene mutations were detected in 30% of endometrioid and 46% of clear cell cancers, as well as in areas of atypical endometriosis that were adjacent to the cancers (36). Many genes expressed in endometriosis are also detected in endometrioid ovarian cancer, but do not overlap with genes expressed in high-grade serous cancers (37). In summary, endometriosis is associated with 3 type I (38) ovarian histiotypes: endometrioid, clear cell, and low-grade serous ovarian cancer (see also Pathology section).

A common mechanism linking endometriosis and PID to ovarian cancer risk may involve the intensive release of cytokines and infiltration of immune cells (macrophages) that accompany inflammation. Some (39,40), but not all (41) epidemiologic data suggest that the use of anti-inflammatory agents, including aspirin and nonsteroidal anti-inflammatory drugs, protects against ovarian cancer development.

Other Risk Factors: Diet, Smoking, Exercise

For the most part, the studies that have investigated whether diet affects ovarian cancer risk have had inconsistent and conflicting results. Any association between diet and cancer risk is likely difficult to decipher given the inaccuracy of food frequency questionnaires and seasonal differences in the supply of fresh food. Several studies have tried to determine whether vitamin A and β -carotene consumption affects ovarian cancer risk, but while some studies suggested a risk reduction, others could not confirm it.

In an Italian study, a diet favoring red meat was reported to confer an increased risk of ovarian cancer (42). However, the California Teachers Study, which had almost 100,000 participants, concluded that dietary factors are unlikely to play a major role in ovarian cancer development. In this study a RR reduction was only found with isoflavones, the phytoestrogens found in soy-based foods, some of which have antiestrogenic effects (RR, 0.6; 0.33–1) (43,44).

The Women's Health Initiative Dietary Modification Randomized Controlled Trial evaluated prospectively the effects of reducing fat intake by at least 20% and increasing consumption of vegetables, fruits, and grains on ovarian cancer incidence in 48,835 postmenopausal women (45). The overall ovarian cancer HR was not statistically different between the 2 groups; however, the HR decreased with increasing duration of intervention: For the first 4 years, the risk for ovarian cancer was similar in the intervention and control groups; but then over the next 4 years, the risk was lower in the intervention group (0.38 cases per 1000 person-years in the intervention group versus 0.64 per 1,000 person-years in the comparison group [HR 0.6; CI, 0.38–0.96]).

Indirect evidence for the effect of diet on the risk of ovarian cancer comes from the fact that women from geographic areas with a low incidence of ovarian cancer who relocate to a high-incidence region (North America, Europe) acquire the same risk as women who were born in that region, and by the increase of ovarian cancer incidence over time in Japan, which is transitioning to a more Westernized eating pattern (46).

Smoking is not generally considered a risk factor for ovarian cancer (47). However, current smoking seems to be associated with an increased risk of developing a mucinous ovarian cancer (OR, 1.78; 1.01–3.15) (48). Smoking cessation reduces this risk back to baseline over 20 years.

Currently, there is no convincing association between physical exercise and ovarian cancer risk and survival (49). An ongoing GOG trial is studying whether regular exercise, a low-fat diet, and high intake of vegetables after primary treatment for ovarian cancer affects recurrence (GOG #225).

In summary, factors that decrease the number of lifetime ovulations reduce the risk of developing ovarian cancer, while hereditary factors increase the risk. From a practical, clinical standpoint, only a positive family history will raise the suspicion of a predisposition to ovarian cancer in an asymptomatic woman.

HEREDITARY OVARIAN CANCER: BRCA AND HNPCC

Biology of BRCA-Associated Ovarian Cancer

The study of familial breast and ovarian cancer began in 1866 when the French physician Paul Broca noted a much larger than expected incidence of cancer in one family. Over 4 generations, 10 out of the 24 women in this family died from breast cancer, while several more individuals of both sexes developed other malignancies. Dr. Broca concluded that this excess of cancers could not reasonably be attributed to chance. Now that mutations in the high-penetrance *BRCA1/2* genes and the MMR gene group associated with Lynch syndrome have been identified, we know that these hereditary mutations are the strongest known risk factors for the development of ovarian cancer. Approximately 15% of invasive epithelial ovarian cancers are estimated to be the result of autosomal dominant genetic factors with high disease penetrance, predominantly germline mutations in the *BRCA1* or *BRCA2* genes (65% to 85%), or in MMR genes (10% to 15%) (50).

The *BRCA* genes are inherited in an autosomal dominant fashion, which means that every first-degree relative of a mutation carrier has a 50% chance of carrying a mutation. The *BRCA* genes function as classic tumor suppressors, with loss of the function of both alleles required for cancer formation. Carriers are initially heterozygous for the *BRCA* gene mutation(s) in all cells and then the sporadic loss of the wild-type allele in epithelial breast or fallopian/ovarian cells results in a predisposition to cancer. The 2 *BRCA* proteins regulate cell cycle checkpoints and gene expression. Their most important function is probably participation in a specific DNA repair pathway, homologous recombination, which is used for the high-fidelity repair of double-strand DNA breaks. Because cells with *BRCA1/2* mutations lack the ability to repair double strand breaks, they have increased genomic instability and a predisposition to malignant

transformation. The ability of cells with *BRCA* mutations to repair DNA cross-links induced by platinum salts is impaired, which is hypothesized to explain the improved chemosensitivity and survival of patients with *BRCA* mutations (see below).

The prevalence of *BRCA1* or *BRCA2* mutations (over 1,000 have been identified) in the general population is about 1:300 to 1:800. However, specific ethnic populations founded by small ancestral groups, such as French Canadians, Icelanders, and Ashkenazi Jews, have a higher mutation rate arising from spontaneous “founder mutations.” For example, 2% to 3% of all Jewish women of Eastern European descent have one of 3 founder mutations (2 in *BRCA1* 187delAG and 5382insC; 1 in *BRCA2* 6174 delT). The cumulative lifetime risk of developing ovarian cancer for women with a *BRCA1* mutation has been estimated at 39% to 54%, and for women with a *BRCA2* mutation, 11% to 23%. The number of *BRCA2*-associated ovarian cancers is smaller overall. In comparison, the lifetime risk for ovarian cancer for women in the general population is 1.4% (51,52). As we understand more about the *BRCA* genes, the various *BRCA1/2* genetic changes have been classified according to their functional effects. Class I mutations are present in 66% of *BRCA1* mutation carriers and class II mutations in 25%, while class II mutations are rare in *BRCA2* carriers (53) (see Table 24.2).

Also, loss of proteins in the homologous recombination pathway and loss of components for the Fanconi anemia pathway, will result in cells with defective homologous recombination that is comparable to cells with a *BRCA* mutation. This phenomenon is referred to as “*BRCAness*” (54). Therefore, while only 13% to 14% of women with ovarian cancer carry germ-line *BRCA1/2* mutations, the TCGA analysis of almost 500 patients revealed that close to half of them had functional defects in one component of the homologous DNA repair pathway (55). Cancers with such functional defects have been hypothesized to exhibit similar clinical behavior as cancers associated with *BRCA* mutations, and means of identifying “*BRCAness*” of a subset of tumors that occur in women who do not carry a germ-line *BRCA* mutation are being sought. However, none of these classifiers have been clinically validated.

Clinical Features of BRCA-Associated Ovarian Cancer

In general, *BRCA* mutation carriers who develop ovarian cancer have a younger age at diagnosis, are more likely to have cancers of high-grade serous histology originating in the fallopian tube, are less likely to have borderline or mucinous tumors, and have a better prognosis than matched controls with sporadic ovarian cancer (50,56–58). A breast cancer precedes the ovarian

Table 24.2 Different Types of *BRCA* Mutations

Mutation Type	Mutation Effect	Mechanisms
Class I mutations	Loss of function mutations	– mRNA nonsense-mediated degradation – Instability of truncated protein – Deletion of regions regulating transcription → These changes result in reduced mRNA transcript, protein level or a truncated nonfunctional protein
Class II mutations	Potentially stable mutant proteins: – dominant-negative functions – partially preserved normal function – loss of function	– missense substitutions – in-frame deletions and insertions – truncating mutations in the last exon of <i>BRCA1/2</i> → these genetic changes might still allow for the expression of a partially functional protein and might have less detrimental effect
Ovarian cancer cluster region mutations (OCCR)	Mutations within nucleotide region c.2831–c.3847; c.6275–c.6401	Mutations occurring in the central region are associated with a higher risk of ovarian and breast cancers compared to mutations outside this region

cancer diagnosis in 37% of *BRCA1*-associated cases and 37% of *BRCA2*-associated cases (53).

In 1996, Rubin and colleagues reported results of a retrospective analysis suggesting that there are distinct clinical and pathologic features of *BRCA1*-associated ovarian cancer (56). Among 53 patients with germline *BRCA1* mutations, the average age at diagnosis was only 48, and the vast majority of cancers were serous adenocarcinomas. Cancers associated with *BRCA1* mutations had a relatively favorable prognosis, with an actuarial median survival of 77 months compared to 29 months for matched controls (Fig 24.6). Boyd et al. performed a retrospective cohort study of invasive ovarian cancers in patients of Jewish origin (67 *BRCA1* and 21 *BRCA2*) (57). The average age at diagnosis was 54 for *BRCA1* mutation carriers, 62 for *BRCA2* mutation carriers, and 63 for Jewish women with sporadic ovarian cancers. The histology, grade, stage, and success of cytoreductive surgery were similar for hereditary and sporadic cases, although there were no mucinous tumors and only 2 clear cell tumors observed among 88 *BRCA*-associated cases, versus 5 mucinous and 7 clear cell tumors among 101 sporadic cases. The median disease-free interval after initial chemotherapy was 14 months for the *BRCA*-associated group and 7 months for the sporadic group ($p < 0.001$). While most series find that *BRCA*-associated cancers are most often of high-grade serous histology, one recent review suggested that *BRCA1* and *BRCA2* associated tumors are similar in histology and grade to sporadic cancers. A recent study of 1,119 *BRCA1/2* associated ovarian cancers (53) reported 67% serous, 12% endometrioid, 2% clear cell and 1% mucinous cancers; the important clinical implication was that women with a nonserous carcinoma should still be considered for *BRCA* mutation testing (59). In a series of *BRCA*-associated ovarian cancers with centralized pathology review (60), cancers in *BRCA* carriers were compared to those in noncarriers. Among 220 women, mutation-associated tumors were of significantly higher grade and stage and less often mucinous, when compared to non-mutation-associated tumors. No mucinous and no borderline tumors were found in the mutation-associated group. Primary peritoneal carcinoma occurred rarely in both groups.

Extending the findings of improved survival of *BRCA*-associated ovarian cancers, a pooled analysis of 26 prospective, international studies published in 2012 found a 5-year overall survival of 36% for noncarriers, 44% for *BRCA1*, and 52% for

BRCA2 mutation carriers. Even after adjusting for age, stage, grade, and histology, women with *BRCA*-mutations had a significantly longer survival, with *BRCA2* mutation carriers having the best prognosis (58). These studies suggest that ovarian cancer developing in *BRCA1/2* mutation carrier have specific clinical characteristics compared to sporadic ovarian cancer. It is probable that the improved survival of women with *BRCA*-associated ovarian cancers is related to the fact that loss of function of *BRCA* proteins, which participate in DNA damage repair, results in a more favorable response to platinum-based chemotherapy.

BRCA1/2 associated ovarian cancers are less likely to have platinum-resistant disease (14.9%) compared to sporadic ovarian cancer (31.7%), and when these patients recur, they tend to have a higher response to second-line platinum-based chemotherapy even in the setting of platinum-resistant disease (50). Platinum salts induce DNA crosslinks, which are recognized by DNA damage repair pathways, and are repaired by nucleotide excision repair and homologous recombination (61). It may be because *BRCA1/2* associated high-grade serous cancers harbor defects in homologous recombination that platinum compounds are more efficient in these cancers (56,58). Indeed, a decrease in *BRCA1* mRNA levels (PCR-based measurement) was associated with a significantly longer survival in 57 unselected ovarian cancer patients (62).

Deficiency in either *BRCA1* or *BRCA2* also causes profound cellular sensitivity to the inhibition of poly(ADP-ribose) polymerase (PARP) (63). The PARP enzyme is essential for the repair of DNA single-strand breaks. PARP inhibition blocks repair of single-strand breaks, and normal cells will compensate by using homologous recombination to bypass these lesions during DNA replication. Since *BRCA*-mutated cancer cells cannot perform DNA repair through homologous recombination, exposure to PARP inhibitors results in their death, while cells with intact homologous recombination pathways survive. This therapeutic mechanism is called “synthetic lethality,” and refers to the concept that 2 defective pathways that do not, individually, affect cell viability, will, in combination, be lethal (63,64). Several PARP inhibitors are in clinical development, and these drugs appear to have preferential single-agent activity in tumors of patients who carry germline *BRCA* mutations.

Genetic Testing/Counseling

BRCA1/2-directed genetic counseling is important because (a) it will help to identify women at risk of having a *BRCA1/2* mutation, (b) it will allow for the implementation of preventive strategies in patients with known *BRCA1/2* mutations and counseling of their families, and (c) it will guide therapy decisions in *BRCA1/2*-associated serous ovarian cancers. Given that a salpingo-oophorectomy significantly reduces the risk of developing ovarian and fallopian tube cancer, it is clinically meaningful to be aware if a woman carries a *BRCA* mutation. While the treatment (carboplatin/paclitaxel) for *BRCA* mutation-associated ovarian cancers is currently the same as treatment for sporadic ovarian cancers, the current development of PARP inhibitors may change this.

The following factors (59) are associated with a 20% to 25% chance of having an inherited disposition to breast and ovarian cancer and are recommended by the Society of Gynecologic Oncologists (SGO) for use in deciding which patients should be screened: Ashkenazi Jewish ancestry, young age at diagnosis, personal history of both breast and ovarian cancer, or a family history of ovarian cancer or breast cancer (particularly multiple first-degree relatives, or relatives with breast cancer at a young age, including paternal relatives), and a relative with a *BRCA1/2* mutation. Women at risk for a *BRCA* mutation should be referred for genetic counseling, since they will have to make difficult decisions about genetic testing, and, especially if a

FIGURE 24.6. Actuarial survival among 43 patients with advanced ovarian cancer and *BRCA1* mutations compared to matched controls without known mutations.

Source: Reprinted with Permission from Rubin SC, Benjamin I, Behbakht K, et al. Clinical and pathological features of ovarian cancer in women with germline mutations of *BRCA1*. *N Engl J Med*. 1996;335:1413–1416.

mutation is found, ovarian and breast cancer screening and risk-reducing strategies including prophylactic surgery. Moreover, *BRCA* mutation carriers have an increased risk of pancreatic cancer (3% to 4%) and melanoma (5%). Considerable expertise and time is necessary to counsel these women well.

If a woman who is found to have a *BRCA1/2* mutation chooses screening rather than prophylactic surgery, most practitioners will follow her with clinical pelvic exams, CA-125 testing, and pelvic ultrasound, but there is no evidence that these are effective screening strategies. Patients should also have regular breast examinations as well as annual mammograms and breast magnetic resonance imaging (MRI). Prophylactic bilateral mastectomy should also be discussed with *BRCA* mutation carriers, and patients should be informed of the techniques available for removing and reconstructing the breast, and the expected psychosocial and sexual effects. Counseling about risk-reducing salpingo-oophorectomy (RRSO) should balance the risks and symptoms associated with surgical menopause with the morbidity and high mortality of advanced serous ovarian cancer.

Most studies have shown that the reproductive and hormonal factors that affect ovarian cancer risk in the general population also affect risk for women who carry *BRCA1* and *BRCA2* mutations. Narod et al., from Toronto, initially reported a 60% reduction in ovarian cancer risk for *BRCA1* or *BRCA2* mutation carriers with OCP use for 6 or more years (65). However, while smaller studies have confirmed this observation, a large population-based study from Israel did not find a protective effect (66); therefore, the use of OCPs as a means to prevent ovarian cancer in *BRCA* mutation carriers prior to oophorectomy has remained controversial. Later, the Toronto group reported results from a greatly expanded database, which included 670 women with a history of *BRCA1*-associated ovarian cancer, 124 with a history of *BRCA2*-associated ovarian cancer, and 2,424 mutation carriers with no history of ovarian cancer (67). Use of OCPs reduced the risk of ovarian cancer in both women with *BRCA1* mutations (OR, 0.56) and in those with *BRCA2* mutations (OR, 0.39). Breast-feeding was also found to be protective for carriers of a *BRCA1* mutation (OR, 0.74). An effect of similar magnitude was seen for breast-feeding in *BRCA2* mutation carriers, but it was not statistically significant (OR, 0.72). Although the Toronto group had previously reported that tubal ligation was protective against ovarian cancer in mutation carriers as well as noncarriers, the association in this expanded cohort was not significant for carriers of either a *BRCA1* (OR, 0.8) or a *BRCA2* mutation (OR, 0.63). Pregnancy, which had previously been reported to be protective for women carrying a *BRCA* mutation (66), was found to be protective for carriers of *BRCA1* mutations (OR, 0.67), but was associated with increased risk for carriers of *BRCA2* mutations (OR, 2.74). The reasons for this are not clear.

It is also important to offer genetic testing to patients with risk factors for a *BRCA1/2* mutation who have already developed ovarian cancer. The identification of a *BRCA* mutation may impact their treatment, since it might indicate an increased sensitivity to platinum compounds in the first- and second-line setting (50) and PARP inhibitors. Also, their unaffected first-degree female relatives have a 50% probability of carrying the same mutation, and can be specifically tested for it. Those first-degree relatives who are found to be *BRCA* negative can be told that they are not at a statistically significant risk of developing ovarian cancer (68), while those who carry the mutation can be counseled on risk-reducing strategies. The SGO criteria used to determine who should be screened for *BRCA1/2* mutations are generally applied to women who have been diagnosed with ovarian cancer as well as to unaffected patients (see above [59]). However, by using these criteria for patients with the disease, practitioners will miss many women who have a *BRCA* mutation. A large study, which screened 1,342 unselected patients from the province of Ontario diagnosed with epithelial ovarian cancer,

reported a mutation frequency of 13.4% (69). This study used multiplex ligation-dependent probe amplification, and, therefore, included the detection of large deletions that normally elude general sequencing. Women with ovarian cancer in their fourth life decade had the highest mutation rate (24%), as did women of Italian (43%), Jewish (30%), or Indo-Pakistani (29%) origin. Most importantly, 8% of the women in the study had no family history of ovarian cancer. Among Ashkenazi Jewish women with ovarian cancer, there is about a 29% to 40% chance that the disease is related to a *BRCA1* or *BRCA2* mutation (66,70). The Australian Ovarian Cancer group detected *BRCA1/2* germline mutations in 22% of patients with high-grade serous cancers, 44% of whom did not have a family history of cancer (50).

Given these findings (50,54,55,69), the current complicated criteria for testing (59), advances in sequencing technology (55), and potential implications for selecting treatments (50,54), it has been suggested that testing for germline *BRCA* mutations should be routinely offered to all women with nonmucinous high-grade epithelial or serous ovarian cancer, regardless of family history. Such strategies are already employed in some Canadian provinces (Ontario, British Columbia) and are being considered in Australia.

Finally, it is important to be aware of legislation that addresses issues of discrimination and privacy that are raised by the prospect of increasingly comprehensive genetic information on each patient. The Genetic Information Nondiscrimination Act (“GINA”) (2008) prohibits health insurers and employers from discriminating on the basis of genetic information (71). Rules governing patient privacy and confidentiality prevent a physician from disclosing genetic test results to a relative. ASCO guidelines suggest that the ethical duty to warn a relative of genetic risk is satisfied if the doctor explains to the patient that a hereditary cancer syndrome has implications for other family members, advises the patient to share information with them, and offers genetic counseling for those family members who are interested and at risk.

Prophylactic Salpingo-Oophorectomy for Prevention of *BRCA*-Associated Ovarian Cancer

Indication for Surgery

There is, at this time, no scientific evidence that the current methods of screening can detect ovarian cancer early. The currently widely used screening procedures (clinical exam, CA-125, pelvic ultrasound) have such low specificity and sensitivity that their utility in detecting ovarian cancer at a curable stage is highly questionable (72). Such screening is even less efficient in young premenopausal women because ovulating women may have functional cysts or a hemorrhagic corpus luteum mistaken for a suspicious mass.

In contrast, the evidence does support the efficacy of RRSO for the early detection of ovarian cancer and its prevention in unaffected patients (73–76). In 2002, 2 large prospective series clearly demonstrated that RRSO reduced the risk of developing müllerian carcinoma (ovarian, fallopian tube, and peritoneal cancer) in patients with *BRCA1/2* mutations (73,74). Kauff and colleagues from Memorial Sloan-Kettering prospectively studied 170 women with either *BRCA1* or *BRCA2* mutations for 6 years. Ninety-eight women who underwent RRSO were compared with 72 women who elected surveillance. As can be seen in Figure 24.7, the RRSO group had significantly fewer *BRCA*-related gynecologic and breast cancers than the surveillance group. Another prospective study, of a larger cohort of women, allowed us to understand the effects of RRSO in *BRCA1* and *BRCA2* patients separately. In this multicenter study of 1,079 patients, RRSO reduced ovarian cancer risk in

FIGURE 24.7. Kaplan–Meier Estimates of the Time to Breast Cancer or BRCA-Related Gynecologic Cancer among Women Electing Risk-Reducing Salpingo-oophorectomy and Women Electing Surveillance for Ovarian Cancer.. $P = 0.006$ by the log-rank test for the comparison between the actuarial mean times to cancer. A Cox proportional-hazards model for multiple end points, which took into account the different proportions of women in the 2 groups who had breast tissue at risk, yielded a hazard ratio for subsequent breast cancer or BRCA-related gynecologic cancer after risk-reducing salpingo-oophorectomy of 0.25 (95% confidence interval, 0.08 to 0.74). Source: From Kauff ND, Stagapan JM, Robson ME, et al. Risk-reducing salpingo-oophorectomy in women with a BRCA1 or BRCA2 mutation. *N Engl J Med*. 2002;346:1609–1615, with permission.

women with *BRCA1* mutations by 85% and reduced breast cancer risk in women with *BRCA2* mutations by 72%. There was also a 39% reduction in breast cancer risk in women with *BRCA1* mutations, and a reduction in gynecologic cancers in women with *BRCA2* mutations but these were not statistically significant. The absence of a significant reduction in ovarian cancer in *BRCA2* mutation carriers was probably attributable to the fact that most women with *BRCA2*-associated ovarian cancer are over 60 years old, while the median age of the women in the study was 46 years (69,75). In another large study coordinated by the Toronto group, 1,828 known carriers of a *BRCA1* or *BRCA2* mutation were identified from an international registry of 32 centers. The overall reduction in risk of müllerian cancers with RRSO was 80%; the estimated cumulative incidence of peritoneal cancer at 20 years after oophorectomy was 4.3%, with most cases occurring less than 5 years after RRSO (76).

Given the strong evidence that RRSO is protective against the development of ovarian cancer, The National Comprehensive Cancer Network (NCCN), the American College of Obstetrics and Gynecology (ACOG) and the Society of Gynecologic Oncology (SGO) (59) have recommended that prophylactic oophorectomy be considered in women with ovarian cancer syndromes at age 40 years or after childbearing is completed. Because *BRCA2* mutation carriers will develop ovarian cancer at an average age of 58, and only 2% to 3% of these women will develop ovarian cancer by age 50 as compared to 10% to 21% of women with *BRCA1* mutations, delaying surgery in *BRCA2* mutation carriers could be considered (69). However, women with *BRCA2* mutations have a 26% to 34% risk of developing breast cancer by the age of 50, and the evidence suggests that the

breast-cancer risk reduction conferred by RRSO is greater when the ovaries are removed earlier (77).

Surgery

RRSO substantially decreases ovarian cancer risk. Some risk of primary peritoneal cancer remains after RRSO although that risk may largely arise from an ovarian remnant, an incompletely removed fallopian tube, or a microscopically metastasized, occult cancer that could not be recognized at the time of surgery.

The informed consent discussion for RRSO surgery should include not only information about the general risks of surgery, but also information about the likely side effects of bilateral salpingo-oophorectomy. Permission to perform a full staging or debulking procedure if cancer is found should also be obtained. The rate of occult cancer detected with RRSO (which requires an additional surgical procedure) can be up to 10% in a tertiary referral center (21,78) though the rate drops to approximately 3% when centers that do not perform an extensive pathologic review of the fallopian tube are included (79). Hysterectomies are not performed routinely, because there are no reports indicating that the intrauterine portion of the fallopian tube gives rise to a fallopian tube cancer. However, hysterectomy may be indicated if there is other uterine pathology, if the uterus contributes to incontinence or bleeding disorders, to reduce endometrial cancer risk for patients with Lynch syndrome who are also at risk for endometrial cancer (see below), or to simplify HRT.

It is usually possible to perform a RRSO laparoscopically as an outpatient procedure. Occasionally a laparotomy will be necessary due to extensive intra-abdominal/pelvic adhesions. After a thorough surveillance of the entire abdominal cavity including the

upper abdomen, peritoneal washings are performed and abnormal areas biopsied. The ureter is visualized and the infundibulopelvic vessels are transected about 2 cm superior to the ovary to assure that the entire ovary has been removed. The tube and the superior branch of the uterine artery are transected very close to the uterine cornu. A frozen section is only prepared if there is a gross abnormality of the ovary or any other suspicious tumor. Random biopsies of the omentum and peritoneum have not been found to lead to improved detection of occult cancers (78). Many patients presenting for RRSO will have had a previous reconstruction of their breast using some variation of a rectus abdominus myocutaneous flap. Since these procedures can lead to umbilical translocation in relation to the aortic bifurcation, higher camera port placement may be required (80). In general, RRSO is associated with a very low risk of operative complications. In a Memorial Sloan-Kettering study, four out of 80 RRSOs performed laparoscopically had complications caused by adhesions and trocar injuries, which are known complications associated with operative laparoscopy (74).

Because high-grade serous “ovarian cancer” is now believed to arise in the fallopian tube, the option of removing the fallopian tube and leaving the ovary *in situ* is being debated. As of this time, this approach is not supported by published data, and we believe that it remains strictly investigational.

Postoperative Results

Women who have chosen to undergo RRSO generally report a good overall quality of life. The surgery is often accompanied by a significant decrease in perceived risk, and therefore a decrease in anxiety (81). Acute surgical menopause, however, can have a significant negative effect on quality of life (82). Surgical menopause affects bone health and can cause a decrease in sexual desire, vaginal atrophy and dyspareunia, affecting sexual functioning and leading to decrease in sexual desire, discomfort, and avoidance of intimacy. Many patients suffer from vasomotor symptoms, such as hot flashes and night sweats, which lead to sleep disturbances. These symptoms can be alleviated but not completely eliminated by HRT (81). It has been reported that short term HRT (approximately 3 years duration) does not negate the protective effect of RRSO on the development of subsequent breast cancer (83). This was confirmed by Eisen et al., who showed that HRT after RRSO is not associated with an increase in breast cancer risk in *BRCA* mutation carriers (84). Still, decision-making regarding menopausal therapies in women with *BRCA* mutations who are at increased risk of breast cancer is challenging because of the theoretical risk that HRT will promote growth of occult breast tumors. Alternative treatments for vasomotor symptoms, such as venlafaxine and gabapentin, should be discussed in counseling.

The Pathologic Examination of Risk-Reducing Salpingo-Oophorectomy Specimens

A family history of ovarian cancer and/or *BRCA* mutation status should be shared with the pathologist, since in patients with benign gynecologic disease only one slide from the fallopian tube and ovary is normally reviewed (21,78). In the setting of a known history of genetic predisposition to breast and ovarian cancer, most pathologists will submit the entirety of the fallopian tubes and ovaries for microscopic examination. The SEE-FIM (sectioning and extensively examining the fimbriated ends) protocol is widely used. Basically, this involves serially sectioning the tube meticulously, stopping before the fimbriae. The fimbria is amputated and sectioned longitudinally, thereby maximizing exposure. Deeper sections need to be obtained if foci of atypia are to be identified histologically. Foci of *in situ* or invasive occult carcinoma may be very subtle, and are often less than 1 mm in maximum diameter. (See also Pathology section.)

Microscopic occult carcinomas have been identified in RRSO specimens in about 2% to 9% of *BRCA* mutation carriers,

generally involving the tubal fimbriae. In one prospective series, 7 ovarian, and 3 tubal carcinomas (and 1 case in which washings showed malignant cells but no primary cancer was identified) were found among 490 women who underwent RRSO (76). Powell and colleagues report that in 111 consecutive *BRCA*-positive patients treated at a single institution, 9% had occult neoplasia (78). Suspicious epithelial cells, clearly distinct from mesothelial cells, are occasionally identified in cytology specimens. Colgan et al. found malignant cells in 3 of 35 pelvic washings. One microscopic ovarian surface carcinoma and 1 *in situ* tubal carcinoma were found; no carcinoma could be identified in the third patient. Twenty-two percent of specimens showed endosalpingiosis (85). Positive cytology specimens only rarely lead to the discovery of early-stage tubal carcinomas (21,78) although sometimes, as mentioned, malignant cells are present in washings at RRSO and there is no identifiable carcinoma by histology (76).

Lynch Syndrome—Hereditary Nonpolyposis Colorectal Cancer Syndrome

Epithelial ovarian cancer is also a component of Lynch syndrome II (Hereditary nonpolyposis colorectal cancer syndrome—HNPCC). In addition to a predisposition to develop colorectal and endometrial cancer, women with this syndrome have a 10% to 13% lifetime risk for developing ovarian cancer (86). Women at risk for Lynch syndrome are identified using either the Amsterdam II or the revised Bethesda criteria, attempting to enrich for patients who are likely to have a hereditary origin of their cancer. However, even though the Bethesda criteria have been revised to improve identification, they may still miss as many as 28% of patients with Lynch syndrome.

Lynch syndrome-related tumors exhibit a lengthening or shortening of DNA repeat sequences, which leads to microsatellite instability (MSI), caused by an inability to repair DNA replication errors. This syndrome is a result of germline mutations in genes involved in the DNA mismatch repair pathway, such as *MSH2* and *MLH1* which account for about 90% of the mutations detected in families with Lynch syndrome, with *MSH2* being particularly associated with an excess of endometrial and ovarian carcinomas. Other genes in the MMR family, including *MSH6*, *PMS1*, and *PMS2*, account for 10% of HNPCC-related cancers (86). To identify patients with HNPCC 2 approaches are used: For MSI analysis, DNA is extracted from macrodissected tumors using paraffin sections, and short tandem repeats are amplified. Immunohistochemical stains are performed for *MSH2*, *MSH6*, *MLH1*, and *PMS2*. If a MMR protein is absent, despite appropriate controls, confirmatory sequencing is performed. MSI can be due to epigenetic changes as well as to Lynch syndrome. For example, *MLH1* promoter hypermethylation or *BRAF* gene mutations can result in MSI.

A recently published French multicenter study reviewed the cancer incidence in 537 families with Lynch syndrome (87). For women in the study, the cumulative risk for Lynch syndrome-associated cancers was 19% by age 50 and 54% by age 70. The age specific cumulative risk for ovarian cancer by age 70 was 20% for *MLH1* mutation carriers, 24% for *MSH2* mutation carriers, and 1% for those with *MSH6* mutations (Fig. 24.8). This study clearly showed that *MSH6* mutation carriers have much lower cancer risks than *MLH1* and *MSH2* mutation. These findings raise the question of whether women with a *MSH6* really need prophylactic surgery, especially if no other family member has been affected by cancer. However, a smaller cohort study did not confirm this low ovarian cancer risk in women affected by *MSH6* mutations and found that a third of cases of ovarian cancer identified among MMR mutation carriers were affected by a *MSH2* mutation (88). This study from the combined Swedish/Danish cancer registry found that the distribution of ovarian

^aSee eTable 3 (available at <http://www.jama.com>) for the number of affected individuals and the number of family members contributing to the likelihood for risk estimation.

FIGURE 24.8. Age-Specific Cumulative Risks of Colorectal Cancer, Endometrial Cancer, and Ovarian Cancer According to Gene for Mismatch Repair Mutation Carriers.

Source: From Bonadona V, Bonaldi B, Olschwang S, et al. Cancer risk associated with germline mutations in MLH1, MSH2, and MSH6 genes in Lynch syndrome. *JAMA*. 2011;305:2304–2310, with permission.

cancer histologic subtypes in patients with Lynch syndrome differed considerably from the sporadic ovarian cancer population. They reported that 35% of the ovarian cancers associated with Lynch syndrome were endometrioid, and 17% were clear cell, both much higher percentages than are seen in sporadic cases.

As with *BRCA1/2* patients, RRSO is a very effective method for the prevention of ovarian cancer in patients with a Lynch syndrome mutation. Preoperatively patients should have a colonoscopy to detect colon cancer, an endometrial biopsy to exclude an occult endometrial cancer, and a vaginal ultrasound to detect any ovarian masses that will affect the surgical approach (minimally invasive vs. open surgery). In a large study combining all Lynch syndrome patients followed at MD Anderson, UCSF, and Creighton University, none of 61 patients who underwent RRSO and a hysterectomy developed ovarian or uterine cancer. However, 12 (5.5%) of the 223 patients who chose surveillance developed ovarian cancer and 33% developed endometrial cancer (89). Consistent with the French study (87), half of the patients who developed ovarian cancer had a *MLH1* mutation and the other half a *MSH2* mutation, while none had a *MSH6* mutation. Clearly RRSO and hysterectomy are efficient in preventing gynecologic cancers in women affected by HNPCC.

A critical question for patients with Lynch syndrome is at what age a hysterectomy/BSO should be performed. Two studies reported that the median age for endometrial and ovarian cancer in these patients is 46 to 48 years and 42 to 48 years, respectively. Moreover, a significant number of the women studied (21% to 42%) developed ovarian cancer before age 40 (88,89). In contrast, the French study found that the risk of developing ovarian cancer for all Lynch syndrome mutation carriers by age 40 does not exceed 2% to 3%. Still, a prudent approach is to perform the hysterectomy and RRSO after the age of 35 (or once childbearing is completed). Obviously, such an early intervention requires extensive counseling, balancing the consequences of surgical menopause treated with HRT with the benefits of avoiding ovarian and endometrial cancer.

For patients with Lynch syndrome who prefer not to undergo prophylactic surgery there is no scientifically proven screening option. Still, according to the NCCN guidelines and most experts, transvaginal ultrasound and CA-125 are acceptable exams in patients with mutations, if the patient is fully aware that these interventions will not necessarily diagnose ovarian cancer early and might even be harmful, due to possible complications of surgical follow-up for a false-positive result (72). However, given that two-thirds of HNPCC-associated ovarian cancers are diagnosed during stage I and II because of their endometrioid and clear cell histology (88,89), a vaginal ultrasound is a reasonable choice for surveillance in a woman who declines prophylactic surgery.

NATURAL HISTORY OF THE DISEASE: PATTERNS OF SPREAD

Mucinous and Endometrioid Ovarian Cancer

Mucinous neoplasms are the largest of all known ovarian tumors. They can reach diameters of 30 to 40 cm, often compressing adjacent organs (Fig. 24.9). Intact removal may be challenging because of the weight and the large veins that drain from the tumor, and because of difficulties visualizing the ureter. Interestingly, the largest tumors are often benign. Indeed, invasive mucinous ovarian cancer is rare because most of the tumors are low grade, or are benign mucinous cystadenomas (80%). High-grade invasive mucinous cancers, however, are very aggressive and resistant to chemotherapy (90). Of all advanced ovarian cancers, 0.5% to 1.5% have a mucinous histology. Most (71%) invasive mucinous tumors found in the ovary are metastasis from the gastrointestinal tract (colon, pancreas, and appendix) so only 29% of all mucinous carcinomas found in the ovary are truly primary mucinous ovarian cancers (90,91).

FIGURE 24.9. A 42-year-old patient with a multicystic adnexal mass originating from the left ovary. The specimen was 20 × 15 cm, weighed 5 pounds. The frozen section returned as a mucinous borderline tumor.

These primary invasive mucinous tumors are often confined to the ovary without surface involvement, and are unilateral (metastases are bilateral) and of a significant size (≥ 13 cm) (91). Often patients with mucinous tumors have an elevated CEA or CA19-9.

Pseudomyxoma peritonei is a condition caused by the production of mucin by glandular cells in the peritoneal cavity. These cells have a benign glandular histology, but their behavior is biologically malignant, since the mucin-producing cells implant diffusely on the abdominal and pelvic peritoneum. They then produce thick mucin that can encase the bowel and pelvic organs, leading to tumor cachexia and bowel obstruction. Usual origins of pseudomyxoma peritonei are currently thought to be appendiceal neoplasms or ruptured benign mucocles of the appendix with secondary involvement of the ovary. Patients with pseudomyxoma peritonei can progress for months or years without symptoms. Although their disease often has an indolent course, it cannot be cured (10-year survival is 60%) (92). Currently, it is recommended that patients receive very aggressive cytoreductive surgery with complete peritonectomy and hyperthermic intraperitoneal chemotherapy (HIPEC) in a specialized center, although there are no randomized data to support this strategy.

Invasive endometrioid ovarian cancer accounts for about 10% of all ovarian carcinomas and occurs most often in perimenopausal patients. These cancers are often associated with endometriosis (33–35). Up to 25% of young premenopausal patients of reproductive age with an endometrioid endometrial cancer have a synchronous early-stage endometrioid ovarian cancer (93).

Because of their size, both mucinous and endometrioid ovarian cancer are likely to be discovered at an early, FIGO I/II, stage. These cancers do not have the pattern of transcoelomic spread along peritoneal surfaces seen with serous cancers. Locally, they are characterized by thick adhesions to the pelvis and can invade adjacent pelvic organs including the muscularis of the colon and the pelvic sidewall. Advanced metastatic endometrioid and mucinous tumors (FIGO III/IV) implant into the abdominal wall, and metastasize to the parenchyma of intra-abdominal organs such as liver and spleen. They can also have early distant extra-abdominal metastases.

Serous Ovarian Cancer

Serous carcinomas originating from müllerian epithelium, including ovarian, peritoneal, and fallopian tube cancers, are characterized by transcoelomic spread (16,94,95). Recently there have been new insights into the origin of serous “ovarian” cancer, and a putative precursor lesion in the fallopian tube, serous tubal intraepithelial carcinoma (STIC), has been identified. It is now believed that most serous “ovarian” cancer originates in the fallopian tube as STIC (21). Often, it is not possible to clearly identify where the serous tumor originated. However, this is not very important from a practical, clinical standpoint since the dissemination pattern and patient survival of the 3 serous-papillary subtypes (ovarian, fallopian tube, peritoneal) are very similar. A recent study (96), as well as clinical experience, suggests that all 3 tumor subtypes grow quickly and disseminate on mesothelial cell-covered body cavities including the peritoneal cavity or pleural space. Extensive surface involvement of the abdominal or pleural cavity will cause ascites and a pleural effusion, respectively. Rarely, serous tumors will metastasize to the mesothelial cell covered pericardium, causing a pericardial effusion.

Ovarian, peritoneal, and fallopian tube cancers have a very distinctive presentation, by virtue of their propensity to exfoliate malignant cells into the peritoneal cavity. The exfoliation of neoplastic cells from the ovarian tumor or the distal fimbriated

FIGURE 24.10. Laparoscopic intraoperative image of the pelvis of a patient with disseminated high volume disease suggestive of ovarian cancer on CT scan. Tumor implants on the sigmoid colon, sigmoid mesentery, pelvic sidewall, ovary, utero-ovarian ligament, bladder peritoneum.

end of the tube is the probable starting point for the cells (21,94). The most common sites involved in locoregional metastasis are the contralateral ovary, the peritoneum of the cul-de-sac, the rectosigmoid colon and its mesentery, which often results in an obliteration of the rectouterine space.

In patients with extensive pelvic disease (Fig. 24.10) the uterus, bladder, peritoneum, sigmoid colon, ovarian tumor masses and appendix become a conglomerate pelvic tumor, and it is very difficult to identify the individual organs or any anatomic borders (97,98). Sometimes the appendix becomes part of a right adnexal tumor mass.

Once the cancer cells detach from the ovarian or fallopian tube tumor, they float in the ascites as single cells or as multicellular spheroids (16). The cells follow the normal clockwise circulation of peritoneal fluid up the right paracolic gutter and to the undersurface of the right hemi-diaphragm, where they may implant and grow as surface nodules. All intraperitoneal mesothelial covered surfaces are at risk, with frequent involvement of the peritoneum, diaphragm, omentum including the hepatic and flexure and splenic hilum, bowel and bowel mesentery, and appendix (95,99). The most frequent site of distant metastasis is the omentum. Other than the contralateral ovary, an omental metastasis is often the largest tumor in the abdominal cavity. Serous cancers initially transform the infracolic omentum, but as the cancer progresses the entire omentum is replaced by tumors (95,100) reaching from the hepatic to the splenic flexure (Fig. 24.11). Because the omentum reaches the spleen in the left upper quadrant there is often a solid tumor at the lower pole of the spleen and at the splenic hilum directly adjacent to the distal pancreas, requiring an *en bloc* resection of the distal pancreas and the spleen to completely clear the left upper abdomen (101–104). In patients affected by extensive disease, the lesser omentum, which is attached to the lesser curvature of the stomach, is also involved. Despite extensive involvement of the omentum by the serous carcinoma there is almost never invasion of the gastric or transverse colon muscularis and it is always possible to remove the tumors without a colon or gastric resection. Also, there is almost never a tumor in the retroperitoneal lesser sac.

Large tumor masses often develop in the right lower quadrant involving the ileocecum, appendix and right ovary. Patients with extensive intra-abdominal tumor involvement sometimes have extensive involvement of the small bowel mesentery, with tumor constricting the blood supply to the bowel and limiting

FIGURE 24.11. Patient with FIGO stage IIIC ovarian cancer with an omental cake. The omentum is completely transformed by tumor nodules. The omentum is lifted superior, towards the patient's head. The omental tumor can almost always be dissected off the transverse colon along an avascular plane (white dotted line) allowing entry into the lesser sac.

mobility of the bowel because of the short mesenteric root, a condition described by its appearance as “rose budding”. Often these tumors are unresectable because they compromise the entire blood supply to the small bowel from the superior mesenteric artery. In very advanced disease, serous cancers tend to agglutinate the loops of small bowel and cause a high-grade bowel obstruction at many levels (jejunum, ileum).

Women with advanced serous ovarian cancer, who have disseminated miliary disease covering the entire peritoneal surface, including the diaphragms, have extensive ascites (105). The ascites contains mostly mesothelial, inflammatory and ovarian cancer cells (16).

Patients with FIGO stage IV disease are a very heterogeneous group because several anatomic locations in the upper abdomen and a malignant pleural effusion define a patient as having a stage IV cancer. Peritoneal-pleural lymphatic communication through the diaphragm allows trans-diaphragmatic spread of tumor into the mesothelial covered pleural space, causing a malignant pleural effusion. Because serous cancers have a preference for implantation on the right diaphragm, most patients have a right sided malignant pleural effusion (37–48%) (106,107). Other FIGO stage IV defining metastasis patterns include parenchymal liver metastasis, supraclavicular/axillary lymphadenopathy, parenchymal lung metastases, mediastinal adenopathy, and distal vaginal or perineal metastasis (106,107). While serous ovarian cancer disseminates extensively within the abdominal cavity, intra-pulmonary metastasis, or other intra-parenchymal or retroperitoneal metastases for example into the liver, spleen, or kidney are rare, and should broaden the differential diagnosis to include a different ovarian cancer histiotype (clear cell, mucinous or carcinosarcoma) or a different tumor origin (gastrointestinal, breast cancer). Advanced low-grade serous cancers, which represent about 9% of all epithelial ovarian cancers (108,109), have a very similar tumor distribution to high-grade serous cancers, with metastasis to the omentum (83%), fallopian tube (63%), pelvic peritoneum (49%), and uterine serosa (46%) (110).

Fallopian tube cancers have a similar spread pattern to ovarian cancer but first invade the tubal muscularis, which is why staging for fallopian tube cancer includes depth of invasion. Schiller and Silverberg (111), in a retrospective review of 76 published cases of obvious early stage fallopian tube

carcinoma, documented the important relationship between the depth of invasion by tumor and survival. A crude 5-year survival of 91% was found for intramucosal lesions, 53% for tumors with mucosal wall invasion, and 25% or less for cases in which the tumors penetrated the tubal serosa. A study by Peters et al. (112) confirmed the importance of the depth of invasion in predicting survival. The pathologist who examines a fallopian tube that contains invasive tumor should provide information on the depth of invasion, the presence of lymphatic or capillary space involvement, and the degree of histologic differentiation. Some studies have reported a higher incidence of lymph node spread in fallopian tube cancers.

Lymph Node Metastasis

Exfoliation and implantation is 1 of 2 primary modes of spread of ovarian cancer. The other is via the retroperitoneal lymphatics that drain the ovary. These follow the superior ovarian blood supply in the infundibulopelvic ligament, which contains the ovarian artery and vein as well as extensive lymphatics, which terminate in lymph nodes lying along the aorta and vena cava up to the level of the renal vessels. The next lymph node stations are at the celiac trunk from where tumor cells may continue up to the mediastinal and supraclavicular lymph nodes. Lymph channels also pass laterally through the broad ligament and parametrial channels to terminate in the pelvic sidewall lymphatics, including the external iliac, obturator, and hypogastric chains (113). Spread may also occur along the course of the round ligament, resulting in involvement of the inguinal lymphatics (these patients are still considered to have FIGO IIIC disease). The principal lymphatic drainage of the ovary and fallopian tube appears to be via the paraaortic lymph nodes. Lymph node metastases are correlated with extent of intra-abdominal disease involvement, and retroperitoneal node involvement has been found in the majority of advanced ovarian cancer cases (114–117).

The initial spread of ovarian cancer, by both the intraperitoneal and lymphatic routes, is clinically occult. As many as 20% of women with what appears to be stage I/II ovarian cancer have widespread disease. The extent of their disease can be detected only by histologic examination of visually normal tissues sampled during careful surgical staging (118). Approximately 10% of patients with cancer that appears to be confined to the ovaries will have metastases to the paraaortic nodes. Many patients with apparently localized disease will also have occult disease in peritoneal washings or in biopsies of the diaphragm and omentum (Table 24.3).

Table 24.3 Subclinical Metastases in Apparent Early Ovarian Cancer

Site	No. of Patients with Involvement	Total Patients	% Involved
Diaphragm	17	223	7.6
Omentum	21	294	7.1

Recurrent Ovarian Cancer

The majority (80%) of patients with advanced ovarian cancer who undergo a combination of platinum- and taxane-based chemotherapy will have a recurrence, despite an initial complete response to primary treatment (106,119,120). Seventy-five percent of all patients have an intraabdominal recurrence; the remainder have extraperitoneal/intrahepatic or distant metastasis with or without intrabdominal recurrence (121). Twenty-two percent of recurrences occur outside the peritoneal cavity. The location of intraabdominal recurrences include the remnants of the omentum, especially at the splenic flexures, the small and large bowel mesentery, and the epiploic appendices, which are peritoneal pouches filled with fat and located along the colon and intraperitoneal rectum.

Following the increased use of intraperitoneal chemotherapy with the publication of GOG #182 (122) several retrospective studies reported a change in the pattern of recurrence. Women treated with intraperitoneal, rather than intravenous, chemotherapy were found to have a higher rate of extraabdominal recurrences, including brain metastasis, pleural effusions, and mediastinal disease (101). Robinson et al. found that women with recurrent ovarian cancer treated with intraperitoneal chemotherapy had a 26% risk of extraabdominal metastasis, while women treated with intravenous chemotherapy had a 7% risk (123). Two further retrospective studies reported even higher extraperitoneal recurrence rates of 41% to 45% with intraperitoneal chemotherapy (101,124). If intraperitoneal chemotherapy is combined with bevacizumab more patients present with recurrent disease in the central nervous system or the skin (123), indicating that bevacizumab also affects the recurrence pattern of ovarian cancer. Since most patients with intraperitoneal chemotherapy receive bevacizumab at some point during their treatment for recurrent disease, it is possible that the variation in pattern of metastasis reported for intraperitoneal chemotherapy is actually caused by bevacizumab.

CLINICAL PRESENTATION AND DIAGNOSTIC WORKUP

The diagnosis and treatment of patients with ovarian masses is difficult because of the diversity of clinical presentations, the plethora of differential diagnoses, and the wide range of therapeutic options.

Clinical Presentation of Patients with a Benign Adnexal Mass or Early-Stage Ovarian Cancer

Almost all patients with small adnexal tumors are asymptomatic, and the mass is usually discovered incidentally during a work-up for other conditions. With increasing size, adnexal masses cause pelvic pressure and pain by compressing surrounding structures. A larger pelvic tumor can cause genitourinary symptoms including urgency, frequency, and dyspareunia. Posteriorly, a fixed pelvic tumor compresses the sigmoid colon, causing severe constipation. These symptoms are essentially similar in both benign disease and early ovarian cancer, and it is impossible to differentiate a benign from a malignant ovarian mass by clinical examination alone. Borderline ovarian tumors, nonserous malignant epithelial ovarian cancer (endometrioid, clear cell, mucinous), and nonepithelial (germ cell, stromal cell) malignant tumors present as large adnexal masses at an early-stage without any further abdominal dissemination.

An ovarian mass becomes a surgical emergency if a patient with an adnexal mass has sudden onset of abdominal pain. The differential includes torsion and possible infarction of the ovarian mass. But severe abdominal pain can also be caused by a hemorrhage inside a cyst, which distends it, or by the rupture of a blood-filled cyst, causing hemoperitoneum. Sudden abdominal pain associated with an adnexal mass is often accompanied by malaise, nausea and vomiting, low-grade fever, and an elevated white blood cell count and C-reactive protein, which are all caused by the peritoneal irritation. In the presence of acute pain, peritoneal signs, rigidity, and rebound tenderness, urgent expert surgical evaluation should be considered. Evaluation is most often performed laparoscopically. Delaying surgery can result in infarction, hemorrhage and peritonitis.

Vaginal bleeding in a patient with an adnexal mass could be an indication of synchronous endometrial and ovarian cancers (93) or a granulosa cell tumor that produces estrogen, causing abnormal bleeding. Sertoli-Leydig cell tumors can lead to virilization.

Clinical Presentation of Patients with Advanced Ovarian Cancer

The clinical presentation of advanced ovarian cancer is varied, and it is often surprising to the treating physician how few symptoms women with advanced ovarian cancer sometimes experience. General, nonspecific symptoms associated with advanced ovarian cancer include anorexia, fatigue, early satiety and loss of appetite. While weight loss is unusual in ovarian cancer because of diffuse ascites production, tumor cachexia can be a presenting sign in patients with high-volume disease and long standing partial bowel obstruction.

Often patients complain of nonspecific pelvic and abdominal symptoms, including bloating and diffuse, dull, constant abdominal pain caused by the infiltration of the peritoneum and the bowel mesentery, or by extensive ascites. Involvement of the small bowel can cause changes in frequency of bowel movements alternating constipation with diarrhea. If the tumor has metastasized to the omentum, patients complain of upper abdominal discomfort with nausea, belching, early satiety and fullness. The abdominal cavity may also be distended by several liters of ascites, which can cause a significant increase in abdominal circumference leading to marked discomfort. Extensive ascites can cause significant fatigue, anorexia, pain, nausea/vomiting, and incontinence. In addition, ascites can cause dyspnea, because the lower lung lobes are compressed by the abdominal distension (105). Signs of bowel obstruction, severe urinary symptoms, intense pelvic pain, and ascites are likely to indicate miliary dissemination on the peritoneal surfaces and large-volume advanced disease.

Because symptoms often develop late, when the cancer is already advanced, ovarian cancer has been called the “silent killer” or “the cancer that whispers”. However, a careful review of symptoms in woman with ovarian cancer has shown that many women have abdominal symptoms, urinary frequency, and pain for 3 months or longer before diagnosis (125). One study suggested that ovarian cancer patients seem to have several symptoms at once (e.g., increased abdominal size/bloating, early satiety, pelvic/abdominal pain, incontinence), which are more severe, more frequent, and of more recent onset than those symptoms reported by patients without cancer who presented to a primary care clinic (125). Other studies have disputed that symptom clusters can aid in recognizing ovarian cancer earlier, and showed that screening for these symptoms adds little to the use of CA-125 and ultrasound (126), indicating that the appraisal of symptoms alone will not lead to an earlier diagnosis (127,128).

The ACOG and SGO (129) consensus guidelines recommend referral to a gynecologic oncologist for postmenopausal women with elevated CA-125, ascites, a nodular/fixed pelvic mass, or evidence of abdominal/distant metastasis. In premenopausal women, a very elevated CA-125, ascites, and evidence of abdominal or distant metastasis should trigger a referral. The guidelines have a positive predictive value of 39.6% for premenopausal women and 64.6% for postmenopausal women (130).

Meigs syndrome is defined as a cytologically benign pleural effusion and ascites, which resolves upon removal of a concomitant ovarian tumor, usually an ovarian fibroma or thecoma. Patients with advanced ovarian cancer sometimes present with a DVT from large tumors pressing on pelvic veins or as part of the hypercoagulopathy associated with advanced-stage cancer (131).

Clinical Exam

A focused clinical exam should begin with an assessment of supraclavicular lymph nodes, a breast exam, and percussion of the lungs to detect a pleural effusion. The abdomen should be evaluated for the presence of an umbilical hernia. The involvement of the umbilicus by an ovarian cancer is colloquially called “*Sister Mary Joseph nodule*,” named after an assistant to Dr. William Mayo, who identified the lesion as a sign of advanced malignancy (132). The abdomen should also be inspected for surgical scars and visible veins (“*caput medusae*”) caused by impaired central venous return from extensive intraabdominal disease, and examined for the presence of ascites, the size and mobility of the adnexal mass, costovertebral angle tenderness from hydronephrosis, and the presence of enlarged inguinal lymph nodes. In a patient with extensive ascites, the bowel floats on top of the ascites leading to central tympany on exam, while in patients with a large tumor the tympany is lateral.

On gynecologic exam, a prominent cystocele could be indicative of ascites. The bimanual and rectovaginal exam should attempt to evaluate and characterize the adnexal mass in respect to size, borders (smooth/irregular), mobility (fixed/mobile), and location. Invasive ovarian cancers often have irregular borders and are often fixed to the pelvic sidewall and fill the cul-de-sac. Pelvic examination findings may also include involvement of the parametrium by tumor, or nodularity of the rectovaginal septum. It may not be possible to differentiate the uterus from the tumor and the cervix is sometimes dislocated anteriorly behind the pubic symphysis. Some ovarian tumors are behind the uterus and can be best palpated with a rectovaginal exam after the bladder is emptied.

Laboratory Tests

A pregnancy test should be part of the work-up for premenopausal women, since uterine enlargement could be due to pregnancy. The laboratory work-up for patients with suspected ovarian cancer generally includes a complete blood count. Patients with ovarian cancer are often hemoconcentrated, while patients with gastrointestinal malignancies are frequently anemic. Patients with ovarian cancer also often have thrombocytosis (a poor prognostic marker) (131) and may have a low albumin level, which is indicative of tumor cachexia and malnutrition and is associated with higher peri- and postoperative morbidity.

The CA-125 tumor marker is elevated in 80% of all patients with advanced epithelial ovarian cancer. In stage I disease, the sensitivity is much lower at 50%, which is one reason that CA-125 is not a good screening method for

early-stage disease (133). However, 80% of patients with ovarian cancer of any stage, who are over 50 years old, have an elevated CA-125. The CA-125 is highest in serous and lowest in mucinous epithelial cancers. Clear cell and endometrioid ovarian cancer often have lower CA-125 values, around 200 U/mL. In premenopausal women, the differential of an elevated CA-125 includes many diseases associated with acute or chronic inflammation, and generally speaking, CA-125 can be regarded as an acute phase reactant. It can be elevated in patients with endometriosis, fibroids, PID, cirrhosis of the liver, systemic lupus erythematosus, and inflammatory bowel disease. Moreover, as a tumor marker, CA-125 is not specific to ovarian cancer, since it is increased, albeit modestly, in most metastatic solid tumors, including gastrointestinal and endometrial cancer. A mathematical, computer-based algorithm, ROCA (Risk of Ovarian Cancer Algorithm), was devised to increase the sensitivity and specificity of CA-125 when it is used for screening. The algorithm involves looking at the changes in levels of CA-125 over time for an individual instead of a single cut-off value as the basis for deciding whether additional tests are needed to look for ovarian cancer. A large UK-based study is currently evaluating this algorithm prospectively.

Patients with mucinous ovarian cancer often have elevated CEA values, but this tumor marker is not specific for ovarian cancer either and is increased in patients with gastrointestinal malignancies, especially colon and gastric cancer.

Imaging of Adnexal Masses, Early and Advanced Ovarian Cancer

In patients with adnexal masses a complete history, physical examination, pelvic ultrasound, and a CA-125 will provide the necessary data to determine if surgery is required. Because history and the clinical exam alone cannot reliably differentiate between benign and malignant masses, imaging is generally performed to help establish a diagnosis.

Ultrasound

Ultrasound can detect and characterize ovarian size and morphology. Benign tumors often appear on ultrasound as unilateral with smooth walls, with a few cysts, no solid elements and an absence of ascites. In general, most benign tumors are cystic and mobile. Defined ultrasound criteria can diagnose functional cysts, dermoids, and endometriomas with a high degree of certainty, allowing the choice of conservative, nonoperative treatment. Functional cysts have thin walls and are fluid filled. Dermoids are often cystic with hyper-echoic areas (teeth). Endometriomas have low level, layered echos (blood) and thick walls. Vaginal ultrasound allows a very good resolution of the ovary but for large ovarian masses, an abdominal scan will complement the vaginal scan.

In contrast, malignant tumors are partially solid and cystic, often bilateral, irregular, fixed, and often accompanied by ascites. Patients with tumors that display these features require surgical exploration. Homogenous solid tumors also require surgical exploration, but the most common finding is an ovarian fibroma.

Sassone developed a model integrating inner wall structure, wall thickness, septa, and echogenicity as sonographic markers of malignancy, and found that in premenopausal women cysts greater than 6 cm should be further investigated for malignancy (134). Indeed, malignant tumors often present as complex masses with partially solid and partially cystic components. Diagnostic models have been developed that integrate grayscale ultrasound, color Doppler ultrasonography, and CA-125. In a pooled estimate of 18 cohort studies of the Sassone model, it

was calculated that its sensitivity and specificity in differentiating between a benign and malignant ovarian mass are 84% and 80%, respectively (135). DePriest presented a model integrating tumor volume, wall structure, and septal structure (136), which was tested in 10 studies and was found to have a pooled estimated sensitivity of 91% and specificity of 69% (135). In 1990, Jacobs introduced the Risk of Malignancy Index (RMI) based on logistic regression analysis that was adjusted 4 times (RMI I–IV) without significant improvements in sensitivity/specificity (137). It uses the product of CA-125 (U/mL), ultrasound scan results, and menopausal status. If a score of 50 is used as a cutoff, the pooled estimate for sensitivity was 91% and for specificity 74% (135).

Sometimes ovarian masses are indeterminate on gray-scale ultrasound providing insufficient rationale to proceed to surgery but are concerning enough that a second imaging test is considered for further characterization.

MRI can contribute to differentiate the nature of a mass as it can differentiate between simple fluid, atypical fluid (mucinous), fresh blood, old hematoma, solid tissue, stromal tissue, and fat. This is why MRI is of help to further characterize a mass when an ultrasound is suboptimal or indeterminate (138,139). As with ultrasound, several criteria have been established to differentiate a benign from a malignant mass, including the presence of septations, solid elements and papillary projections, and solid tissue intensity on T2-weighted MRI. Injection of gadolinium contrast agents further assists to characterize an adnexal mass because solid malignant components within a mass take up the contrast. This allows for better resolution aiding in the differentiation of cystic from solid lesions, especially endometriomas, stromal cell tumors, and teratomas. The pretest probability to detect a borderline/malignant tumor increased from 32% to 77% (95% CI, 69% to 85%), with a positive result for malignancy in the MRI diagnosis, and decreased to 4.8% (95% CI, 3% to 6%), with a negative result (140). Given these sensitivity and specificity, MRI is a reasonable test to predict if a mass is benign or malignant but will not be able to differentiate between borderline and invasive tumors. A meta-analysis found that the average sensitivity and specificity to identify a borderline/malignant tumor from a benign tumor was 92% (95% CI, 89% to 94%) and 85% (95% CI, 82% to 87%), respectively. While the sensitivity is similar to that reported by ultrasound, the specificity of MRI outperforms that of ultrasound imaging. A comparison of color Doppler, CT scans, and MRI showed that of all 3 modalities, contrast-enhanced MRI is most helpful in further characterizing an adnexal mass (138). In a premenopausal woman with an indeterminate ultrasound and a negative contrast-enhanced MRI, the risk of malignancy is 2%, while a positive MRI increases the risk of malignancy in the same patient to 80%.

Given the higher *a priori* probability that a mass in a premenopausal patient suggests a benign mass, a reasonable approach is to further characterize an indeterminate mass by MRI (138,139). If the MRI suggests a benign mass, the patient can be followed with a combination of clinical exam, serial ultrasounds, and CA-125 every 3 to 6 months to capture a malignant adnexal tumor not detected during the initial work-up. If the mass is stable, the follow-up interval can be extended. Still, it is important to stress to the patient that while gray-scale ultrasound can be used to characterize many ovarian masses reliably, only histological examination can confirm the diagnosis.

Computed Tomography/CT–Positron Emission Tomography Scan

Computed Tomography allows for detection and further characterization of an adnexal mass but performs less well than MRI

as a secondary imaging modality after gray-scale ultrasound. Even when intravenous contrast is given, CT offers lower soft tissue contrast than MRI (138,139). CT has a sensitivity of 87% and a low specificity of 16% in differentiating a benign from a malignant ovarian mass (141).

Because of reasonable costs and wide availability, CT scanning is currently the preoperative imaging modality most often used in patients with a high clinical suspicion for ovarian cancer. Frequently patients are discovered to have an adnexal mass or advanced disease after a CT scan of the abdomen and pelvis performed to work up unspecific clinical symptoms. In the pelvis, a CT scan allows for characterization of the adnexal mass and any involvement of surrounding organs (bladder, sigmoid, ureter, pelvic sidewall involvement). In the upper abdomen retroperitoneal adenopathy, omental involvement, and intrahepatic liver involvement can be detected reliably by CT scans with intravenous contrast (132,142).

Preoperative CT scans can identify the presence of disease in anatomic regions that are difficult to resect (e.g., stomach, lesser sac, liver, small bowel mesentery, adenopathy above the renal vessels). Bristow and colleagues identified 13 diagnostic features and calculated a predictive score to predict the chances of optimal cytoreduction (143). The score integrated 13 factors: peritoneal thickening, peritoneal implants greater than 2 cm, small and large bowel mesenteric disease greater than 2 cm, omental extension to stomach, spleen, or lesser sac, extension of the tumor to the pelvic sidewall/parametria/hydroureter, large-volume ascites, supra- and infrarenal lymph-adenopathy, diaphragm involvement, inguinal canal disease, liver lesions greater than 2 cm, and porta hepatis/gall bladder disease. Using this model, the authors were able to predict surgical outcome with 93% accuracy (143). However, multi-institutional validation showed an accuracy of only 34% to 46% (144). This study identified disease on the diaphragm and large bowel mesentery implants as the only statistically significant predictors of suboptimal cytoreduction, but even limiting the score to these 2 factors there was still a 33% false-positive rate (144). A Japanese study from Osaka University has combined diffuse peritoneal thickening, pelvic lymph node involvement, bowel encasement, and cul-de-sac implants to predict suboptimal debulking and found an improved accuracy of 88% (145), but their score has not yet been validated. Because surgical outcome depends on so many other factors than anatomical disease distribution (comorbidities, surgeon philosophy, advanced surgical techniques) preoperative CT scanning poorly predicts surgical resectability. Therefore, for most patients surgical evaluation of the peritoneal cavity is required to evaluate resectability of disease (146). Still, a patient whose CT scan indicates clearly high-volume ovarian disease should be evaluated carefully before a decision is made to proceed with primary debulking.

Positron emission tomography (PET) has been integrated with CT scan for the diagnosis of ovarian cancer and evaluating disease recurrence (142,147). CT/PET combines the high anatomic resolution afforded by the CT scan with a functional study of tumor fluoro-deoxy glucose (FDG) uptake. While PET scans have very high sensitivity, the low specificity leads to false-positive results because of increased FDG uptake in benign metabolically active tissues and inflammatory changes. In a single institution prospective study with 101 patients, a combined CT/PET scan had a sensitivity of 100% and specificity of 92% in diagnosing a tumor that had a high RMI score correctly (148). CT/PET scans seem to be especially useful in further characterizing recurrent disease in patients with rising CA-125 levels. In a retrospective study PET/CT showed a sensitivity of 82% and a specificity of 87% in correctly identifying recurrent disease which was superior to CA-125 or CT/MRI scans used alone (147).

Magnetic Resonance Imaging—MRI

While CT provides good spatial resolution, MRI is a nonradioactive imaging modality allowing for excellent soft tissue contrast resolution. In addition to being useful in diagnosis of an indeterminate ovarian mass (138,139), as described above, MRI is also an excellent modality to characterize nonadnexal pelvic pathology (e.g., diverticulitis) and to further characterize the upper abdominal disease extent of an ovarian cancer. The T1-weighted MRI images after administration of contrast (gadolinium) allow for detection of peritoneal metastases and bowel implants. It also allows determination whether the bowel mesentery is involved by cancer, whether a liver tumor is benign or malignant, is on the surface of the liver or intrahepatic, and whether the cancer involves the diaphragm. MRI is better than CT or ultrasound in the diagnosis of small peritoneal metastases, but CT imaging is superior in identifying involvement of the omentum by ovarian cancer (141).

In recurrent cancer, MRI is especially useful for differentiating between postsurgical changes and a recurrence on the vaginal dome, small bowel mesentery, splenic hilum, liver surface, or diaphragm. The reported sensitivity of MRI for recurrent ovarian cancer ranges from 62% to 91% and the specificity is between 40% and 100% and is mostly dependent on tumor size (142).

A new MRI technique dynamic, diffusion-weighted MRI (DWI), measures the diffusion of water molecules in the tissue. It is used in imaging of prostate cancer and is currently being tested for the evaluation of indeterminate ovarian masses, to evaluate small tumors and peritoneal implants for early recurrence, and follow chemotherapy treatment response (149).

Screening

No current screening modalities either individually or in combination (CA-125, pelvic ultrasound, pelvic examinations) have been shown to decrease the risk of death from ovarian cancer. Because ovarian cancer has such a low prevalence (1 case/2500 women per year), screening low-risk asymptomatic women would require a test or combination of tests with high sensitivity, specificity, and both positive and negative predictive value. Several studies have shown that if asymptomatic women were screened for ovarian cancer, between 5 and 33 operations would be required to find one invasive ovarian cancer (72,126,148,150). This situation is primarily caused by the high false-positive rate of ultrasound.

The Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial randomized 78,216 women to either undergo annual screening with CA-125 and ultrasound or to have usual medical care (72). The results showed that screening does not improve mortality from ovarian cancer and found a greater cause-specific mortality in the intervention group (RR, 1.18; 0.82–1.71), driven by the morbidity associated with undergoing more operations. False-positive screening results were returned in 3,285 patients, 1,080 (32.9%) underwent surgery and of these 15% or 163 women had a major complication. The number of patients diagnosed in late stage ovarian cancer was similar in the screening and observation group, suggesting that screening does not detect ovarian cancer at an early stage. The absence of an expected stage-shift was also confirmed by a large Japanese screening study (150).

Even in women who carry a *BRCA1* or *BRCA2* mutation, annual pelvic exams, CA-125, and ultrasound have not been shown to be useful for screening (76). However, such screening is still recommended by the NCCN for high-risk women, and is carried out by many clinicians in the absence of an alternative. The inability to detect early ovarian cancer using a yearly

screening approach is probably due to the very fast growth rate of serous carcinoma once it is fully transformed, which reduces the time during which screening can detect preinvasive or early invasive ovarian cancer (96). Another reason that screening tends to be ineffective may be the extent of ovarian cancer disease heterogeneity. Large-scale screening trials using the ROCA algorithm described above are still underway.

In summary, pelvic exams, CA-125, and ultrasound have not been shown to prevent mortality from ovarian cancer. If a woman wants to reduce her risk, tubal ligation, or OCP may currently be her best chance of primary prevention.

Diagnosis

The correct clinical diagnosis of an ovarian mass is difficult and requires considerable experience and clinical judgment (Table 24.4). Age is a very important factor in assessing an adnexal mass, since many ovarian tumors have a predilection for a particular age group. In premenarchal girls, an adnexal mass is often germ cell in origin, while young women in their reproductive years are most likely to have benign disease. In postmenopausal patients, a complex adnexal mass is particularly concerning for an epithelial cancer, as a normal postmenopausal ovary is atrophic and small ($1.5 \times 1 \times 0.5$ cm) (Table 24.5). These clinical situations will most often result in surgery.

The adnexal mass in the reproductive age woman causes the biggest differential challenge. The differential diagnosis of an adnexal mass/cyst is described in Table 24.4. There are several categories of benign masses, including functional cysts, adenomas, germ cell tumors (mature teratomas), sex cord stromal tumors (fibromas), and endometriosis. A pedunculated fibroid is often interpreted as an adnexal mass. Infectious causes include PID, appendicitis, and diverticulitis. For women in their reproductive years, the decision to pursue surgery will depend on clinical suspicion as detailed above and desire for future fertility.

In some patients there is no distinct adnexal mass but a conglomerate tumor in the lower abdomen. The differential for this includes an advanced ovarian cancer, an advanced endometrial cancer/sarcoma, colon, and retroperitoneal tumors. A metastatic breast, colon, or lung cancer tumor should be considered in the presence of an atypical pattern of metastasis, abnormal mammogram or chest x-ray. While ovarian cancer is much more prevalent in postmenopausal women, the most common cause of an adnexal mass in a postmenopausal patient is still a benign cyst. This is either caused by the hormone imbalance during perimenopause or develops postmenopausally driven by hormones secreted by the postmenopausal ovary. In postmenopausal women, simple unilocular cysts could be monitored but women with solid or complex masses are offered surgery. Depending on the level of suspicion for cancer, surgery may begin with a minimally invasive approach that can be converted to an open procedure if the frozen section suggests a borderline tumor or malignancy.

When formulating a diagnosis, the most important factors to consider are the patient's age, history, clinical exam, serum, and imaging studies. However, the fear of not detecting a malignancy, which could delay diagnosis or lead to inadequate surgery has shaped the clinical response to adnexal masses. The current treatment paradigm is that every postmenopausal woman with a solid adnexal mass should have a surgical exploration to obtain histology.

Given that early-stage ovarian cancer has a much better prognosis than advanced-stage disease, many operations are performed with the goal of “catching” a cancer early. Because only histology can exclude the presence of an ovarian cancer, about 5% to 10% of all women will, sometime during their lifetime, undergo surgery to rule out an ovarian cancer despite the fact that most adnexal masses are benign.

Table 24.4 Differential Diagnosis of an Adnexal Mass

Definition	Description	Mean Age	Clinical Presentation	Imaging	Therapy	Comments
Ectopic pregnancy	Tubal pregnancy, most common in the fimbriated end	Reproductive age women	Positive pregnancy test. History of PID, tubal surgery, fertility treatment or previous ectopic pregnancies. Pelvic pain, anemia	Pelvic ultrasound	Methotrexate or laparoscopy with salpingectomy or salpingostomy, laparotomy if hemodynamically unstable	Clinical emergency. 10%–15% recurrence risk
Physiologic, functional cysts	Follicular cyst—preovulatory cyst Corpus luteum cyst—postovulatory cyst caused by hemorrhage or cyst formation. Theca lutein cysts are caused by hCG stimulation of the ovary. “Other”: paratubal cysts, hydrosalpinx	Reproductive age women	Depending on size, lower abdominal pain, dyspareunia, signs of latent torsion. On exam freely mobile and unilateral. May present as an acute abdomen when ruptured, torsed or infarcted	Pelvic ultrasound. Often > 7cm	Persists for weeks. Oral contraceptives might cause involution/resolution and help with the diagnosis. If a cyst does not resolve within 8 weeks, laparoscopy should be considered	Most frequent benign masses in reproductive age woman. A bleeding corpus luteum can cause an acute abdomen, anemia, and hemoperitoneum. Hydrosalpinx is acystic dilatation of the fallopian tube caused by PID, ectopic pregnancy, endometriosis or fallopian tube cancer
Polycystic ovaries	Endocrine disorder: Multiple follicle cysts enlarging the ovaries to 2–5 their normal size	Reproductive age woman	Irregular menstrual cycles, anovulation, amenorrhea, acne, hirsutism, subfertility, metabolic syndrome	Pelvic ultrasound, hormonal tests (DHEA-S, androstenedione, testosterone, FSH). Glucose-tolerance test	Oral contraceptives, metformin, glitazones, weight loss, clomiphene, spironolactone	Often associated with peripheral insulin resistance. Higher risk of endometrial hyperplasia and endometrial cancer
Serous and mucinous cystadenomas	Serous—Cystic: Thin walled, unilocular. Mucinous – cystic thin walled but may be multicystic		Serous 5–20 cm, mucinous up to 40 cm	Pelvic/abdominal ultrasound	Laparoscopic drainage and removal or laparoscopic cystectomy	May present with torsion or rupture. Cystadenofibroma is a mixed tumor
Germ cell tumors	Benign: Teratomas/Dermoids. Malignant: immature teratoma/dysgerminoma	Young reproductive age patients	Bilateral in 20%	Ultrasound. Might show calcifications on X-ray or CT. Solid, partially cystic	Laparoscopic cystectomy removing the entire capsule. If malignant salpingo-oophorectomy, staging	
Sex cord stromal cell tumors	Benign: Fibromas, Thecomas, Brenner cell tumors Malignant: Granulosa cell tumor, Sertoli-Leydig cell tumor	30–menopause, but also postmenopausal patients	Solid, firm tumors resembling fibroids. May produce hormones: estradiol, inhibin. May cause irregular bleeding, uterine hyperplasia	Ultrasound/CT: Solid homogeneous tumors. Granulosa cell tumors are heterogeneous and often rupture	Laparoscopic or laparotomy for ovarian cystectomy or oophorectomy depending on size	In a postmenopausal patients benign stromal cell tumors are preoperatively often interpreted as being malignant. Often the CA-125 is normal or not too high
Peritoneal inclusion cysts	Cystic	Any age	History of multiple pelvic/abdominal surgeries or recurrent pelvic infections or peritoneal dialysis	Ultrasound: multiple thin walled cysts, CT, MRI	Observation <i>versus</i> ultrasound or CT-guided aspiration with cytology. Surgical intervention for severe symptoms or hydronephrosis. High perioperative morbidity (bowel, ureter injury)	
Fibroids	Benign. Broad ligament or pedunculated fibroids misdiagnosed	30–55 yr	Often asymptomatic. Degeneration or infarction can occur and cause acute pain	Ultrasound, rarely CT or MRI	Observation versus surgical intervention with myomectomy or hysterectomy	Common in African-American women. Often pedunculated fibroids are mistaken for an adnexal mass

Endometriosis	1–10 cm endometriotic cysts filled with blood, adherent to surrounding organs. Often bilateral. Endometriotic implants occur in the pelvic peritoneum including the cul-de-sac and bladder peritoneum. Nodularity of the uterosacral ligaments	30–45 yr	Pelvic pain. Dyspareunia. May have cyclical pain with menses, infertility, and dyspareunia. May present with acute pain from rupture, rarely torsion. CA-125 100–300 U/mL	Pelvic/abdominal ultrasound. Diagnostic laparoscopy	Conservative treatment. Anti-inflammatory drugs, OCP, GnRH analogues. Laparoscopy with removal of endometriotic nodules. Extent of surgery depends on symptoms and desire for future fertility	Common in White nulliparous women. Ovarian endometrioma is also called a “chocolate cyst”
PID/Salpingitis	Tubo-ovarian abscess complicate PID in 15% of all women	Young sexually active patients	History of PID, Pelvic pain, malaise, vaginal discharge, cervical motion tenderness. Fever, leukocytosis, CRP ↑, CA-125: 100–500 U/mL. Coagulopathy if septic	Ultrasound showing one or more masses that are homogenous, cystic, possibly with air fluid levels and septations	Combination antibiotic treatment, CT-guided abscess drainage. Laparoscopy or laparotomy if abscess cannot be drained or if the patient has signs and symptoms of sepsis	High recurrence risk
Appendicitis and appendiceal abscess	Appendicitis right sided tenderness, rebound	Younger patients	Fever, guarding, rebound tenderness. Malaise, RLQ pain, nausea, vomiting, absence of vaginal discharge. Pain migration. leukocytosis, CRP ↑, CA-125–100 U/mL	Ultrasound and CT imaging with contrast. No distinct mass. Features consistent with abscess: enhancement, irregular borders	Laparoscopic surgery.	Difficult differential in children and young woman. Consider PID and pregnancy.
Diverticulitis and diverticular abscess	Diverticulitis mostly in the sigmoid colon causing left sided pain	Elderly patients			Combination antibiotic treatment, CT-guided abscess drainage. Surgery if patient has signs and symptoms of sepsis and for definitive treatment	Presentation in very old patients might be subtle. High recurrence risk
Colon cancer			Anemia, irregular stools. Induration and irregularity. Family history.	Sigmoidoscopy/ colonoscopy		60–70% occur on the left side but cecal cancer can present as right adnexal mass
Early invasive epithelial ovarian cancer	Early serous ovarian cancer, endometrioid or clear cell ovarian cancer		CA-125 ↑ only in 50%	Papillary surface excrescences, areas of necrosis, internal solid elements	Surgical intervention: Consider starting with a laparoscopy to establish a diagnosis. Referral to Gynecologic Oncologist for full staging	Differential of ovarian malignancy: invasive serous cancer, endometrioid, clear cell cancer. Borderline tumors
Advanced invasive epithelial ovarian cancer	Serous carcinoma with ascites and metastasis to upper abdomen	Postmenopausal women	CA-125 ↑ in 80%	Suspicious adnexal mass and ascites, upper abdominal disease	Exploratory laparotomy, staging, tumor debulking. Referral to Gynecologic Oncologist	
Metastasis	Gastric, colon, breast, and uterine cancer		CA-125 can be elevated. Other tumor markers might be helpful (CEA, CA19-9, CA15-3)	Bilateral solid complex masses in patient with prior cancer history	Excision can be considered for symptomatic relief or if it is the only site of metastatic disease	Poor prognosis compared to ovarian cancer
Rare differential diagnoses	– Pelvic kidney – Disseminated abdominal tuberculosis: Young woman unlikely to have ovarian cancer from endemic areas, populations at risk, ascites, CA-125 ↑, absence of a dominant adnexal mass.					

Table 24.5 Age Considerations When Deciding if a Mass is Malignant

History		
Age Pregnancy Menopausal status	Premenarchal	Germ cell tumors, mature teratomas, rhabdomyosarcomas
	Young reproductive age (15–25 yr)	Functional cysts, ectopic pregnancy, PID/salpingitis/TOA, dermoid, appendicitis/appendiceal abscess, polycystic ovaries, juvenile granulosa cell tumor, dysgerminoma, endodermal sinus tumor, tuberculosis
	Middle reproductive age (25–35 yr)	Endometriosis, functional cysts, polycystic ovaries, serous/mucinous cystadenomas, PID/salpingitis/TOA Sertoli-Leydig cell tumor
	Advanced reproductive age (35–45 yr)	Stromal cell tumors, fibroids, peritoneal cysts, adult granulosa cell tumor
	Perimenopausal (46–52 yr)	Functional cysts, fibroids, ovarian cancer, endometrial cancer
	Postmenopausal (<52 yr)	serous/mucinous cystadenomas, ovarian cancer, colon cancer, benign stromal cell tumors, diverticulitis/diverticular abscess, fibroids

Differential Diagnosis

Malignant ascites is most often found in women with ovarian cancer, but patients with metastatic breast, pancreatic, and gastric cancer can also present with ascites. Patients with gastrointestinal malignancies and ascites tend to have concomitant intrahepatic metastasis. Therefore, in patients with extensive ascites and CA-125 values around 200 U/mL, other cancers should be considered. Reviewing patients with ascites who presented to an oncology clinic, Ayantunde (105) found diagnoses to be, ovarian cancer (37%), pancreaticobiliary cancer (21%), gastric cancer (18%), colon cancer (4%), and breast cancer (3%). Nonmalignant causes of ascites include pancreatitis, tuberculosis, hepatitis, systemic lupus erythematosus, cirrhosis, and Meigs Syndrome. A paracentesis will both establish a diagnosis of malignancy, and improve the dyspnea, pain, nausea, and vomiting that the patient may be experiencing as a result of large-volume ascites.

While serous ovarian cancer disseminates extensively within the abdominal cavity, it rarely metastasizes elsewhere. Imaging studies that suggest intra-pulmonary metastasis or intra-parenchymatous metastases in the liver, spleen or kidney especially in the absence of significant intraperitoneal disease, should broaden the differential diagnosis to include a different ovarian cancer histotype (clear cell, mucinous or carcinosarcoma) or a different tumor origin (gastrointestinal, breast cancer). Bilateral ovarian tumors may also be a sign that the ovarian tumors are of metastatic origin. Gastric cancers tend to cause drop metastases to the ovary, referred to as a Krukenberg tumors. Gastrointestinal malignancies can metastasize to the ovary due to its extensive blood supply, and these cancers are important differential diagnoses for women presenting with disseminated intra-abdominal disease on imaging. Indeed, 10% of all colon cancers are metastatic to the ovary and the ovarian tumor is often bigger than the primary colonic tumor. Patients who present with predominantly gastrointestinal symptoms, anemia, a high CEA, low CA-125, and a positive hemocult test should undergo an esophagogastroduodenoscopy (EGD) and a colonoscopy with

biopsies. A CA-125/CEA serum ratio greater than 25 has high discriminative power to differentiate between ovarian and colon cancer (151,152). In patients presenting with colon cancer with peritoneal and ovarian metastasis, the median survival is 10 months.

Ovarian cancer is the most common primary nonbreast second malignancy after treatment for breast cancer. Indeed, a history of breast cancer is associated with a 2- to 4-fold increase in the risk of developing ovarian cancer. However, breast cancer can also metastasize to the ovary, and is the most frequent (84%) primary cause of ovarian metastasis of non-GI origin (153,154). Metastasis of breast cancer to the ovary was found at autopsy in 23% to 39% patients dying of breast cancer.

When evaluating a patient with a history of breast cancer and an adnexal mass to determine if an ovarian mass is a breast cancer metastasis or a new ovarian cancer, the stage and histology of the previous breast disease should be considered. Patients with stage IV breast disease are much more likely to have distant metastasis, and lobular breast cancer metastasizes more often to the ovary than invasive ductal cancers. Most patients with ovarian metastasis from breast cancer are premenopausal (77%) and present with abdominal distension in the absence of ascites. Often these patients have bilateral ovarian involvement (64%) a high CA15-3 and a low CA-125. On the other hand, patients with breast cancer and abdominal carcinomatosis can have a high CA-125, which makes the differentiation from ovarian cancer challenging. On pelvic ultrasound, breast cancer metastases to the ovary are more solid appearing than primary ovarian cancer, which is often multicystic. The benefit of surgery in the treatment of breast cancer metastatic to the ovaries has not been proven, and may be limited to the palliation of symptoms by removing a single mass. Retrospective studies have suggested a possible survival benefit for surgery in patients with no residual disease after the operation, but found no benefit in the setting of widely metastatic disease (155). The 5-year survival for women with ovarian metastasis from breast cancer is 26%, while it is 8% and 1% for those with ovarian metastasis from colorectal and gastric cancer, respectively, much lower than the median survival for primary ovarian cancer (153).

STAGING

The widely used 1988 FIGO staging system for ovarian cancer is presented in Table 24.6. Of note, both paraaortic and inguinal lymph nodes are included in FIGO stage IIIC disease, whereas mesenteric lymph nodes (e.g., nodes in the mesentery of the colon) are considered FIGO stage IV disease. Details of surgical staging are discussed in section “Surgery.”

A slight modification of the FIGO staging for fallopian tube carcinoma, as proposed by Alvarado-Cabrero et al. (156) is presented in Table 24.7. This is similar to staging of ovarian cancer for advanced stages, and emphasizes the importance of tumor invasion into the muscular wall.

SURGERY

Introduction and Definitions

Surgery is a cornerstone of therapy for women with ovarian cancer and plays an important role at every treatment stage. Surgery is usually performed during the initial treatment of patients newly diagnosed with ovarian cancer for the purpose of pathologic diagnosis, cytoreduction, symptom relief, and staging. Indeed the FIGO staging system requires that

Table 24.6 Carcinoma of the Ovary: FIGO Nomenclature (Rio De Janeiro, 1988)

Stage I	Growth limited to the ovaries
IA	Growth limited to one ovary; no ascites present containing malignant cells. No tumor on the external surface; capsule intact
IB	Growth limited to both ovaries; no ascites present containing malignant cells. No tumor on the external surfaces; capsules intact
IC ^a	Tumor either stage IA or IB, but with tumor on surface of one or both ovaries, or with capsule rupture, or with ascites present containing malignant cells, or with positive peritoneal washings
Stage II	Growth involving one or both ovaries with pelvic extension
IIA	Extension and/or metastases to the uterus and/or tubes
IIB	Extension to other pelvic tissues
IIC ^a	Tumor either stage IIA or IIB, but with tumor on surface of 1 or both ovaries; or with capsule(s) rupture; or with ascites present containing malignant cells or with positive peritoneal washings
Stage III	Tumor involving one or both ovaries with histologically confirmed peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes. Superficial liver metastases equals stage III. Tumor is limited to the true pelvis, but with histologically proven malignant extension to small bowel or omentum
IIIA	Tumor grossly limited to the true pelvis, with negative nodes, but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces, or histologically proven extension to small bowel or mesentery
IIIB	Tumor of one or both ovaries with histologically confirmed implants, peritoneal metastasis of abdominal peritoneal surfaces, not exceeding 2 cm in diameter; nodes are negative
IIIC	Peritoneal metastasis beyond the pelvis >2 cm in diameter and/or positive retroperitoneal or inguinal nodes
Stage IV	Growth involving one or both ovaries with distant metastases. If pleural effusion is present, there must be positive cytology to allot a case to stage IV. Parenchymal liver metastasis equals stage IV

^aIn order to evaluate the impact on prognosis of the different criteria for allotting cases to stage IC or IIC, it would be of value to know if rupture of the capsule was spontaneous or caused by the surgeon, and if the source of malignant cells detected was peritoneal washings or ascites.

surgery be performed to confirm the histologic diagnosis and to determine the true extent of the disease. In the recurrent disease setting, surgical biopsy can confirm a diagnosis and the removal of an isolated mass may render a patient macroscopically tumor-free. In patients with the extensive tumor dissemination typical of advanced disease, removal of tumor masses (“debulking”) accomplishes significant symptom relief from tumors externally pressing on organs in the pelvis or the upper abdomen. Finally, limited surgery may have a role for palliation of bowel obstruction in select patients with recurrent disease.

Because the most important prognostic factors in ovarian cancer are the FIGO stage and the success of debulking surgery, patients with ovarian cancer will benefit from treatment by physicians familiar with the surgical management of this disease.

Table 24.7 Modified FIGO Staging for Fallopian Tube Carcinoma^a

Stage 0	Carcinoma <i>in situ</i> (limited to tubal epithelium ^b)
Stage I	Growth limited to tube
Stage IA	Growth limited to one tube without extension through or onto serosa, ascites containing malignant cells, or positive peritoneal washings
Stage IA-0 ^c	Growth limited to one tube with no extension into lamina propria ^b
Stage IA-1 ^c	Growth limited to one tube with extension into lamina propria ^a but no extension into muscularis
Stage IA-2 ^c	Growth limited to one tube with extension into muscularis
Stage IB	Growth limited to both tubes without extension through or onto serosa, ascites containing malignant cells, or positive peritoneal washings
Stage IB-0 ^c	Growth limited to both tubes with no extension into lamina propria ^b
Stage IB-1 ^c	Growth limited to both tubes with extension into lamina propria ^a , ^b but no extension into muscularis
Stage IB-2 ^c	Growth limited to both tubes with extension into muscularis
Stage IC	Tumor either stage IA or IB but with extension through or onto tubal serosa or with ascites containing malignant cells or with positive peritoneal washings
Stage I(F)	Tumor limited to fimbriated end of tube(s) without invasion of tubal wall
Stage II	Tumor involving one or both fallopian tubes with pelvic extension
Stage IIA	Extension and/or metastasis to uterus and/or ovaries
Stage IIB	Extension to other pelvic tissues
Stage IIC	Tumor either stage IIA or IIB with ascites containing malignant cells or with positive peritoneal washings
Stage III	Tumor involving one or both fallopian tubes with peritoneal implants outside pelvis, including superficial liver metastasis, and/or positive retroperitoneal or inguinal nodes. Tumor limited to pelvis except for histologically proven extension to small bowel or omentum
Stage IIIA	Tumor grossly limited to pelvis with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces
Stage IIIB	Tumor involving one or both fallopian tubes with grossly visible, histologically confirmed implants of abdominal peritoneal surfaces, none >2 cm in diameter. Lymph nodes are negative
Stage IIIC	Abdominal implants >2 cm in diameter and/or positive retroperitoneal or inguinal nodes
Stage IV	Growth involving one or both fallopian tubes with distant metastases including parenchymal liver metastases. If pleural effusion is present, fluid must be positive cytologically for malignant cells

^aAs suggested by Alvarado-Cabrero et al. (156).

^bModification in terminology.

^cModifications to accommodate subsets of tumors that otherwise cannot be assigned a stage or to distinguish among subsets that may differ in their associated prognosis.

Table 24.8 Terms for Common Surgical Procedures, as they are used in this Chapter

Procedure	Definition
Paracentesis	Drainage of presumed malignant fluid/ascites in a patient with intra-abdominal tumor masses to establish a diagnosis before initiation of chemotherapy with cytology or to provide symptomatic relief.
Biopsy	Biopsy of disseminated disease or an adnexal mass to establish a pathologic diagnosis before initiation of chemotherapy.
Primary cytoreductive surgery	Initial laparotomy to establish a diagnosis, stage and attempt maximal tumor debulking to microscopic disease before the initiation of first-line chemotherapy. Also called “primary debulking” by some physicians.
Interval cytoreduction or Interval debulking	Cytoreductive surgery after a biopsy only or a primary suboptimal debulking followed by induction chemotherapy.
Second-look surgery	Surgery performed at the completion of primary chemotherapy in patients who do not have evidence of disease by CT scan or CA-125 to determine if there is residual disease in order to plan for additional chemotherapy. Currently rarely performed.
Secondary cytoreductive surgery	Surgery in a patient with recurrent disease who has completed primary treatment, including primary debulking ± chemotherapy, and had been without evidence of disease. The procedure is most commonly performed for platinum-sensitive patients with oligometastatic disease. Also called “primary debulking” by some physicians.
Palliative surgery	Surgery performed to relieve symptoms, most commonly performed for a malignant bowel obstruction with the goal to remove the obstruction or perform a diversion. Not primarily intended to remove tumors.
Complete debulking Result: no macroscopic disease	Complete resection [156]: Cytoreduction of all tumors independent of preoperative tumor load to microscopic residual disease at the completion of surgery – no gross residual tumors left. R0 resection.
Optimal debulking. Result: macroscopic disease up to 1 cm	Minimal residual [156]: Macroscopic disease up to 1 cm in diameter after primary surgery. Also called by some physicians “optimal cytoreduction”. R1 resection.
Sub-optimal debulking. Result: macroscopic disease >1 cm	Gross residual [156]: Primary cytoreduction resulting in macroscopic disease larger than 1 cm in size at the end of surgery. R2 resection.

The terms for common surgical procedures, as they are used in this chapter, are defined in Table 24.8.

Early-Stage Ovarian Cancer

In current clinical practice, optimal staging in early ovarian cancer includes careful inspection, palpation, and biopsies of peritoneal surfaces (diaphragm, paracolic gutters, bladder and cul-de-sac peritoneum), pelvic and diaphragmatic washings,

removal of the affected ovary, an infracolic or infragastric omentectomy, and a systematic pelvic and paraaortic lymph node dissection (157). An appendectomy can, though rarely, change the final staging (158). Preserving the contralateral ovary and the uterus in young patients desiring fertility is considered acceptable in the treatment of early-stage epithelial ovarian cancer.

The thorough surgical staging of early-stage ovarian cancer is important to establish the correct stage for determining prognosis and choice of therapy (chemotherapy vs. observation). A prospective randomized trial of patients with FIGO stage I-IIA disease (ACTION trial: (159,160)) indicated that complete surgical staging was statistically significantly associated with better outcomes. In this trial, patients were randomly assigned to adjuvant chemotherapy or observation after they had undergone either complete or incomplete staging surgery. Although the trial was not designed to compare different surgical staging procedures (and extent of surgical staging was not randomized), a subgroup analysis found that patients with a poorly differentiated tumor in the optimally surgically staged group (n=78) had a significantly longer ($p<0.009$) 10-year cancer-specific survival of 85% compared to 56% in patients who were not completely staged (n=78) which is logically attributable to their higher risk of undetected residual disease. This improved outcome was independent of age, presumed stage, histology and whether or not chemotherapy was given (160). The benefit of adjuvant chemotherapy was found to be restricted to patients with incomplete surgical staging, and incompletely staged patients with a poorly differentiated grade III tumor were found to derive the greatest benefit from adjuvant chemotherapy. Predictors of unappreciated residual disease after primary surgery, which leads to upstaging, include a high preoperative CA-125 level, positive cytology, and grade III disease (158).

The surgical approach to staging of early ovarian cancer will depend on patient comorbidities and the number of previous abdominal surgeries, as well as on the minimally invasive surgery training and skills of the surgeon. Retrospective studies suggest that both a minimally invasive approach and an open laparotomy allow for comprehensive surgical staging. Lymph node counts and the size of the omental specimen obtained are similar for both procedures. Given that bulky disease is only rarely detected in early-stage ovarian cancer patients, a minimally invasive surgical approach, which tends to involve more time in the operating room, but less blood loss and a shorter hospital stay than open surgery (161). A concern with laparoscopy is the possibility of port site metastasis, although this risk seems to be small (>1%) and such metastases are often a sign of disseminated intra-abdominal disease (162). Open surgery may have benefits including shorter operating room time, less advanced equipment, and less requirement for specialized surgical training. In early ovarian cancer, restaging involves multiple biopsies of the abdominal and pelvic peritoneum, as well as an oophorectomy, omentectomy, pelvic and paraaortic lymph node dissection, and pelvic and diaphragmatic washings for cytology. Patients who do not want to preserve fertility will have a hysterectomy and removal of the contralateral ovary.

In conclusion, in most cases unstaged patients with presumed early-stage ovarian cancer should be restaged or given adjuvant chemotherapy if staging is not feasible.

Role of Lymph Node Dissection in Early Ovarian Cancer

When treating both early and advanced ovarian cancer, a surgeon must decide whether to perform a lymph node sampling, limited to the removal of enlarged or palpably suspicious lymph nodes or a systematic lymph node dissection, removing

all visible lymph nodes within defined anatomic borders (113). Dye studies have shown that the lymphatic drainage of the ovaries originates under the ovarian surface. Lymph fluid drains predominantly superiorly, along both ovarian vascular pedicles (163,164). On the left side the lymphatics follow the infundibulopelvic vein until it drains into the left renal vein. The high left infrarenal, paraaortic lymph nodes often harbor lymph node metastasis and are a known site of (isolated) recurrence. The right infundibulopelvic vein and its accompanying lymphatics reach the inferior vena cava about 1 cm below the right renal vein. Cancer cells are then able to continue traveling along a net of lymphatic vessels covering the inferior vena cava and the interaortocaval space to lymph nodes at the base of the celiac axis, and then through the caval opening in the diaphragm into the chest reaching mediastinal or prescalene lymph nodes. Secondary lymph drainage routes are along lymphatics draining inferiorly through the utero-ovarian ligament to lymph nodes in the broad ligament, and along the external iliac artery to the round ligament to inguinal lymph nodes. This spread pattern explains why one sometime detects inguinal lymph node metastasis in patients with ovarian cancer. Minor lymph drainage is also to lymphatics along the internal iliac artery or lymph nodes in the obturator fossa (163,164). Ovarian lymph drainage does not reach the uterus, possibly explaining why one rarely sees intrauterine or cervical metastasis in serous ovarian cancer.

In patients with early ovarian cancer, it is recommended that both the pelvic and paraaortic lymph nodes should be removed when a systematic lymph node dissection is performed. However, given the lymphatic drainage of the ovaries, the removal of high paraaortic lymph nodes is the most important (116). The anatomic borders of a pelvic lymph node dissection are laterally, the external iliac artery and the genitofemoral nerve that travels on the psoas muscle; superiorly, the bifurcation of the external and internal iliac artery to the inguinal ligament; and medially, the anterior division of the hypogastric artery and the ureter (Fig. 24.12). After elevating the external iliac vein, the obturator fossa and the obturator nerve are exposed and then cleared of lymph nodes superior to the nerve. To enable the right paraaortic lymph node dissection the descending colon and terminal ileum are mobilized by incising the peritoneum

FIGURE 24.12. View into the right pelvis after a laparoscopic pelvic lymph node staging. The borders of a pelvic lymph node dissection are lateral the genitofemoral nerve, medial the superior vesical artery, posterior the obturator nerve, and superior the bifurcation of the external and internal iliac artery. In this specific patient 13 pelvic lymph nodes were removed from this side.

around the cecum to expose the inferior vena cava and interaortocaval space. Starting the dissection on the right common iliac artery, the precaval fatty tissue containing lymph nodes is removed from the common iliac artery up to the right renal vein, taking great care not to injure the ureter, renal vessels, and duodenum. To remove the left paraaortic lymph nodes, the fat/lymph node containing tissue lateral to the aorta between the bifurcation of the left common iliac artery and the left renal vein is removed. Although it is rarely necessary, the inferior mesenteric artery can be ligated to accomplish a high paraaortic dissection. Because the lymph nodes rest on top of the lumbar vertebral bodies great care must be taken not to injure the lumbar veins. Other complications of the surgery include vascular and ureteral injuries and lymphocele formation. Some authors recommend a more extensive lymph node dissection behind the vessels and posterior to the obturator nerve (28), but there is little evidence that this more extensive dissection is of diagnostic or therapeutic benefit.

Several retrospective studies have indicated that the rate of positive lymph nodes in patients, of all FIGO stages, who undergo a systematic pelvic and paraaortic lymph node dissection is 25% to 53%, with most of the positive lymph nodes found in the high paraaortic and interaortocaval regions (114–117). Because imaging and intraoperative palpation of lymph node beds have a low sensitivity and specificity for the detection of lymph node metastasis, several studies have investigated the role of a systematic pelvic and paraaortic lymph node dissection. In a prospective trial, Maggioni and colleagues randomized 310 patients with early, FIGO stage I and II ovarian cancer who had undergone optimal surgical debulking to receive either a systematic lymph node dissection or lymph node sampling (118). Patients with all major histologic subtypes were represented in the study: serous (39%), endometrioid (21%), mucinous (13%), and clear cell tumors (13%). Positive lymph nodes (which upstage a patient to stage IIIC) were found in 9% of patients in the sampling group, and in 22% of the systematic lymph node dissection group ($p < 0.05$), suggesting that 13% were upstaged because of the lymph node dissection. Of all patients in the study with negative lymph nodes, 66% of the patients in the control arm and 51% in the systematic lymphadenectomy arm received chemotherapy ($p < 0.03$), suggesting that in an unstaged patient, physicians tend to err on the side of over-treatment. The patients in the systematic lymph node dissection arm spent an average of 90 minutes longer in surgery, lost 300 mL more blood, and received significantly more blood transfusions (22% vs. 36%, $p < 0.05$). Both groups had similar rates of postoperative complications. There was no difference in progression-free survival (PFS) or overall survival (OS) between the 2 groups, but the study was underpowered for the detection of a small benefit.

Of note, patients with initial clinical stage I/II ovarian cancer upstaged to FIGO stage IIIC disease only by retroperitoneal lymph node involvement have much better 5-year PFS and OS than stage IIIC patients with intraperitoneal disease (165). Review of the large GOG #182 trial analyzed patients who underwent cytoreduction to microscopic disease. The median PFS was 21 months for patients with positive lymph nodes and intraperitoneal disease greater than 2 cm before surgery, 29 months with negative lymph nodes and disease greater than 2 cm, and 48 months for patients who had positive lymph nodes but preoperative intraperitoneal disease less than 2 cm (166). The rate of positive lymph nodes is very low in mucinous ovarian cancer. A lymph node dissection probably can be omitted in these cancers (114,167).

In summary, systematic lymph node dissection provides important prognostic and staging information for patients with suspected early-stage ovarian cancer, which assists with decisions about adjuvant chemotherapy.

Advanced Epithelial Ovarian Cancer

Rationale for Surgical Debulking in Advanced Ovarian Cancer

Surgical debulking is central to the initial management of advanced FIGO stage III/IV ovarian cancer, and extent of residual disease after surgery is the only prognostic factor under the control of the operating surgeon. The concept of removing widely disseminated tumors within the abdominal cavity is specific to epithelial ovarian/fallopian/peritoneal, and appendiceal cancers. It is very unusual to attempt tumor debulking in patients with metastatic colon, breast, or gastric cancer. One reason that the surgical debulking of ovarian cancer is technically feasible is that serous ovarian cancer is usually confined within the peritoneal borders of the abdominal cavity. It spreads along the peritoneal, diaphragmatic surfaces without deep invasion (16) into abdominal organs, and this allows dissection along a surgical plane between an organ and the attached tumor. For example, while the omental tumor is very large and often densely attached to the transverse colon, it is rarely necessary to perform a transverse colon resection and it is almost always possible to sharply dissect the tumor off without injuring the colon muscularis (Fig. 24.11). The omental tumor often reaches the splenic hilum and distal pancreas but rarely invades these organs. While ovarian tumors can occlude the pelvis completely and transform the pelvic peritoneum into thick tumor plaques, the pelvis can usually be completely cleared of tumors with a modified posterior exenteration (97). Serous ovarian cancer tumors never extend via direct invasion beyond the lining of the peritoneal surfaces, and a retroperitoneal dissection allows the entire tumor-covered peritoneal reflection to be removed (Figs. 24.13 and 24.14). In contrast, colon and

FIGURE 24.13. Specimen from a modified posterior pelvic exenteration. *En bloc* resection of sigmoid colon and its mesentery, uterus, parametrium, and tumor-covered pelvic peritoneum (cul-de-sac, pelvic sidewall, bladder).

FIGURE 24.14. Pelvic floor after a modified posterior exenteration with *en bloc* resection of bilateral ovarian tumors, tubes, sigmoid colon, uterus, and pelvic peritoneum including the cul-de-sac and pelvic sidewall peritoneum, as well as the inferior bladder peritoneum. Red vessel loops are on both ureters. The stapled rectum is outlined with a white circle. View prior to primary end-to-end stapled anastomosis.

breast cancers often grow retroperitoneally, making a complete resection much more challenging.

Several theories have been put forward to explain the strong association of surgical debulking with patient survival. Large bulky tumors may contain necrotic or hypoxic areas that have a low growth fraction and are resistant to chemotherapy. Optimal debulking could then theoretically drive remaining microscopic cells into the cell cycle and into becoming more susceptible to cytotoxic chemotherapy. Smaller postoperative tumor volume may decrease the chance of acquiring more mutations which promote chemoresistance.

In a patient who has an incidentally discovered “low tumor volume” ovarian cancer after an oophorectomy or a “simple” TAH/BSO, restaging (reoperation to accomplish complete surgical staging) and debulking is almost always recommended to evaluate the true extent of the disease and determine whether it is advisable to withhold chemotherapy.

In advanced “high tumor volume” ovarian cancer staging takes place as part of the initial debulking surgery, with the goal of removing all visible disease and, possibly, implanting a port for intraperitoneal chemotherapy (122). In patients with extensive tumor dissemination combined with a chronic bowel obstruction the cancer leads to tumor associated cachexia with a catabolic metabolic status causing adverse metabolic consequences and limiting the patient’s ability to maintain a reasonable nutritional status. In patients with extensive tumor dissemination, removal of tumor masses (“debulking”) accomplishes significant symptom relief from tumors externally pressing on organs in the pelvis or the upper abdomen. Surgical tumor debulking will also reduce ascites production and improve the nutritional and functional status of the patient, resulting in a higher quality of life and improved immunocompetence.

Overall, there is no uniform surgical approach to the treatment of advanced ovarian cancer. Patient (age, nutritional status, comorbidities) and intraoperative factors (disease location, adhesions from previous surgeries, intraoperative stability/anesthesia, blood loss) will determine the extent of surgical resection in the individual patient. It requires significant surgical training and experience to successfully remove pelvic and upper abdominal disease with a low complication rate. In Europe a gynecologist generally collaborates closely with a general surgeon who usually performs the bowel resections and upper

abdominal debulking (e.g., diaphragm stripping, splenectomy). In North America, the majority of debulking, including gastrointestinal procedures, is performed by a gynecologic oncologist with the consultation of a hepatobiliary surgeon should extensive mobilization of the liver or a liver resection be necessary. While the comparative efficacy of these 2 approaches has never been studied, studies on both sides of the Atlantic have shown that high volume centers have a higher rate of optimal surgical debulking in advanced ovarian cancer. The resectability of extensive disease with acceptable morbidity is likely to reflect a combination of surgical experience, technique, anesthesia care, critical and postoperative care, and nursing. Optimal debulking rates of up to 70% to 80% have been reported in various centers (103,104,168,169) but 50% is an accepted quality measure (157). Several centers have shown that a dedicated surgical team and a multidisciplinary effort can improve a program's complete and optimal cytoreduction rates over time. Size and tumor distribution at the beginning and end of surgery should be carefully documented in the operative report in order to define the 2 most important prognostic factors (stage and residual disease).

While surgical debulking plays a very important role in the management of ovarian cancer, patients with very extensive carcinomatosis and extensive upper abdominal disease and/or mesenteric involvement tend to obtain limited benefit from primary debulking procedures as many will be suboptimally debulked. Surgery alone is never curative in advanced cancer, and therefore should only be attempted as part of a treatment concept including postoperative chemotherapy. As discussed below, it is not possible to predict with high accuracy the patients who can be optimally debulked. Neither CT nor PET has a high enough specificity, to predict which patients can be optimally debulked (144), and sometimes only the direct visualization of tumor distribution by laparoscopy provides the necessary information. Moreover, heroic attempts to remove unresectable tumors will not benefit patients.

The characterization of surgical outcome based on the amount of residual disease at the end of surgery is an accepted measure of surgical success, with the caveat that tumor measurements have a high degree of interobserver variability (170).

While many surgeons had previously recommended a maximal debulking effort for patients with advanced ovarian cancer (e.g., Meigs 1934), it was a retrospective study by Griffiths (171) in 1975 that showed an inverse relationship between residual tumor size and survival. Primary surgery, which attempts maximal tumor debulking has never been subjected to a rigorous randomized trial. However, several retrospective studies and meta-analyses have reported the prognostic value of residual disease for both PFS and OS (90,106,107,120,168,172–174). In 1992, Hoskins and colleagues (173,174) reviewed survival and surgical results in 2 GOG studies which enrolled patients with FIGO stage III and IV disease (GOG 52, 97). Defining 3 different groups (microscopic vs. <2 cm vs. >2 cm residual disease), the authors found that survival is inversely related to the volume of residual disease at the end of surgery. At least as important was their finding that, in patients with residual disease greater than 2 cm, size of residual disease was not correlated with survival.

In the largest (4312 women) phase III ovarian cancer trial ever performed to date (GOG 182), the Gynecological Cancer InterGroup studied the addition of a third chemotherapy group to the standard carboplatin and taxol regimen in stage III/IV cancer (395). While the addition of a third drug did not show any benefit, the extent of cytoreductive surgery was significantly correlated with PFS and OS. Patients with FIGO stage III and IV who had no macroscopic disease at the end of surgery, minimal residual (<1 cm), or gross residual disease had a median PFS of 29, 16, and 13 months, respectively, and a median OS of 68,

44, 30 months, respectively. Breakdown by stage is shown in Figure 24.15.

The improved survival seen with benefit of complete tumor resection also applies to the subgroup of patients with FIGO stage IV disease. Winter, reviewing the experience of the GOG #111, #132, #152, #162, showed that patients with residual disease greater than 5 cm, multiple stage IV defining sites of metastasis (parenchymal liver disease, pleural effusion), and clear cell/mucinous ovarian cancer had a significantly worse survival (106) (Fig. 24.16). The median PFS and OS for stage IV patients whose tumor was reduced to microscopic disease was better than that for patients with any amount of residual disease. Patients with residual disease of 0.1 to 1.0 cm and 1.1 to 5.0 cm had comparable survival, and patients with residual tumor bigger than 5 cm had the worst prognosis. These data have been interpreted to suggest that, even in patients with FIGO stage IV disease, cytoreduction to microscopic disease should be the primary goal at initial surgery. A positive association of largest residual disease with survival was confirmed upon review of 3 prospective phase III AGO trials (AGO-OVAR #3, #5, #7) (107).

An important question is whether every patient benefits from surgical debulking independent of the extent of disease at the beginning of surgery. In GOG #52, patients with a large-volume disease at the beginning of surgery, who were optimally debulked using an aggressive upper abdominal procedure still had a worse survival than patients who had low-volume disease to begin with, even if the surgical outcome was similar (174). On the other hand, in a Mayo clinic review of 194 patients with stage IIIC ovarian cancer, those who required aggressive surgical procedures to achieve an optimal debulking result had a disease-specific 5-year OS similar (46% vs. 47%; $p = 0.8$) to that of patients who underwent less aggressive surgical resections to achieve an optimal result (104). Du Bois and colleagues, summarizing the AGO experience from 3 prospective phase III trials (AGO-OVAR #3, #5, #7) with identical inclusion criteria, concluded that complete surgical debulking improves prognosis in any FIGO substage but cannot completely overcome the prognostic impact of preoperative disease load (120). In summary, both the preoperative tumor burden, including the extent of upper abdominal disease, and the amount of surgical resection and subsequent residual disease appear to influence the PFS and OS of patients with advanced ovarian cancer.

Consistent with the smaller studies discussed above, Bristow and colleagues (168) confirmed, in a meta-analysis of 81 studies, that survival is associated with the amount of residual disease, with a median OS of 22.7 months for patient cohorts with 25% or less maximum cytoreduction and 33.9 months for patient cohorts with 75% or greater rates of maximal cytoreduction. Each 10% increase in the proportion of patients who had undergone maximal cytoreduction was associated with a 5.5% increase in median cohort survival time. In summary, complete resection of all visible tumors at primary debulking surgery is, together with disease stage, the most important independent prognostic factor in epithelial ovarian cancer. Therefore, the goal of cytoreductive surgery for patients with advanced-stage FIGO III/IV ovarian cancer should be, whenever feasible, the complete cytoreduction of all visible disease.

The demonstration of improved outcome with radical debulking suggests that patients should be counseled regarding this option. However, it is important to remember that while we justify surgical debulking because it provides symptom relief and it has been shown, in numerous retrospective reviews, to be associated with improved survival, the clinical benefits of radical surgery in ovarian cancer have never been studied in a prospective randomized trial.

Surgical Debulking—Pelvic and Upper Abdominal Procedures

The surgery of patients with advanced ovarian cancer should start with a vertical midline incision from the pubic symphysis to above the umbilicus. This allows visualization of the entire abdominal cavity, including the diaphragms and permits the safe resection of upper abdominal disease. With a careful exploration of the abdominal cavity the surgeon will be able to evaluate the extent of the disease. Particularly careful attention should be paid to the upper abdomen, since the disease distribution in that region will often determine if a patient can be optimally debulked. It is almost always possible to completely remove even the most extensive disease in the pelvis (97). Pelvic and diaphragmatic washings and biopsies of suspicious peritoneal surfaces (e.g., paracolic gutters) should be performed. Patients with advanced ovarian cancer but low-volume disease should have comprehensive staging including a total abdominal hysterectomy, bilateral-salpingo-oophorectomy, and infragastric omentectomy between the hepatic flexure and the splenic hilum. If the patient can be rendered macroscopically disease-free a pelvic and high paraaortic lymph node dissection is reasonable (116), but this procedure remains controversial (see below).

Patients with advanced ovarian cancer and high volume disease usually have extensive tumor burden in the pelvis with encasement of the reproductive organs and sigmoid colon (Fig. 24.10). This requires a modified posterior exenteration,

an *en bloc* resection of the tumor-studded bladder, peritoneum, uterus, sigmoid colon, and proximal rectum, as well as ovarian/fallopian tube masses, cul-de-sac tumors, and possibly the appendix (Figs. 24.13 and 24.14). Low colorectal anastomosis (97), a procedure some gynecologic oncologists call a modified posterior exenteration, should follow; a colostomy is rarely required in patients with serous cancers. Performing a rectosigmoid colectomy as part of the pelvic debulking is often the only option if complete cytoreduction is to be achieved, and is a superior alternative to peritoneal stripping (98). The possible complications of an extensive radical pelvic dissection include pelvic abscess, sepsis, and an anastomotic leak. Patients with serous ovarian cancer who require a modified posterior exenteration often require one or more upper abdominal procedures as well (e.g., a splenectomy, diaphragm peritonectomy/resection, liver resection, and dissection of the porta hepatis) if a complete surgical debulking is to be accomplished (101–104).

The decision to perform extensive upper abdominal surgery often depends on the philosophy of the surgeon in regard to the specific value of upper abdominal surgery and the general value of debulking surgery for ovarian cancer. Centers that are very aggressive surgically report that they perform at least 1 extensive upper abdominal procedure in about 50% of FIGO stage IIIC ovarian cancer cases, as part of their attempt to render as many patients as possible tumor free. This may include a splenectomy with or without a distal pancreatectomy,

diaphragm peritonectomy/resection, liver resection, and dissection of the porta hepatis (101–104). Still, extensive involvement of the upper abdomen with disease may preclude an optimal debulking.

Magtibay and colleagues reported on 112 patients operated at the Mayo clinic who underwent a splenectomy as part of the ovarian cancer debulking effort (175). The most common indication was metastatic involvement (46%), perisplenic involvement from an omental tumor that reached the splenic hilum (42%), and intraoperative trauma (13%). In this large series complications included wound infections (6%), postoperative pneumonitis (4.5%), thromboembolic events (8%), and sepsis (4.5%). The overall perioperative mortality was 5%. Patients undergoing splenectomy should be vaccinated 2 weeks before or after surgery to reduce the risk of overwhelming postsplenectomy infection that can develop into septic shock. Pneumococcal, hemophilus B, and meningococcal vaccinations are recommended.

Role of Lymph Node Dissection in Advanced Ovarian Cancer Surgery

A prospective randomized Italian trial of 427 patients with advanced ovarian cancer (stages IIIB–IV) compared an extensive systematic lymph node dissection with resection of enlarged (“bulky”) lymph nodes and concluded that positive lymph nodes are a negative prognostic marker but that systematic lymph node dissection did not contribute to the benefit of optimal tumor debulking. Systematic lymph node dissection improved PFS (median PFS, 22 vs. 29 months), but not OS (median OS, 59 vs. 56 months) (116). The addition of systematic lymph node dissection resulted in a greater blood loss, more transfusions, and added operative time. The perioperative and late morbidity of a systematic lymph node dissection was 28%, while it was 18% in the control arm. Most of the morbidity was caused by lymphocyst formation and lymphedema. Therefore, even in experienced hands a systematic lymph node dissection carries significant morbidity, which should be factored into decision making. The study took over 12 years to recruit patients from 13 centers and 63% had residual tumor at the end of surgery.

However, it is worth noting that 63% of the patients in the study had residual tumor after their debulking surgery. The German AGO retrospectively reviewed data (AGO-OVAR #3,5,7) from 3 large phase III trials, which studied chemotherapy in advanced epithelial ovarian cancer (117). They found that in the subgroup of patients with no residual disease and no enlarged lymph nodes, a systematic lymph node dissection was associated with a significant survival benefit (median OS, 108 vs. 83 months) (Fig. 24.17) (117).

At this time, however, there is no convincing data that lymph node dissection has a therapeutic survival benefit in advanced ovarian cancer. The current literature suggests that in advanced ovarian cancer, enlarged/suspicious lymph nodes should be removed as part of tumor debulking, and that a systematic pelvic and paraaortic lymph node dissection might therapeutically benefit patients who previously had been optimally debulked to microscopic residual disease. The results of an ongoing large international phase III trial in patients with advanced ovarian cancer who were debulked to microscopic disease and randomized to a systematic lymph node dissection or sampling, should be able to clarify the role of a lymph node dissection.

Neo-Adjuvant Chemotherapy

The EORTC-GCG and NCIC performed a phase III trial randomizing 718 patients with FIGO IIIC or IV ovarian cancer to neo-adjuvant platinum-containing chemotherapy, followed by interval debulking or primary debulking surgery, followed by platinum-based chemotherapy (152). The largest residual tumor was less than 1 cm in 80% of patients treated with the neo-adjuvant approach while this was only accomplished in 42% of all patients with upfront debulking. There was a trend towards less blood loss, and fewer postoperative infections and thromboembolic complications in the neo-adjuvant treatment group and the patients undergoing neo-adjuvant chemotherapy had a shorter operative time. Most importantly, there was no difference in PFS and OS between the 2 groups, and this was independent of the rate of optimal debulking accomplished in a specific center (Figure 24.18). This study started a heated discussion on the role of neo-adjuvant chemotherapy and the best timing of radical debulking in the upfront treatment of ovarian cancer (176,177). The study was criticized for its low PFS and OS results, but most patients had an adverse prognosis to begin

FIGURE 24.17. OS after lymphadenectomy (LNE) or no LNE in patients with no gross residual tumor and without preoperative/intraoperative clinically suspect lymph nodes.

Source: Reprinted with permission from du Bois A, Reuss A, Harter P, et al. Potential role of lymphadenectomy in advanced ovarian cancer: a combined exploratory analysis of 3 prospectively randomized phase III multicenter trials. *J Clin Oncol.* 2010;28:1733–1739.

with: 74% had tumors larger greater than 5 cm (61% >10 cm) in size, indicating that study participants had widely metastatic, very advanced disease. Another criticism was the low rate of optimal debulking. There are no preoperative factors or imaging studies (144) that could be used to predict the success of interval cytoreduction. In patients with extensive tumor burden, ascites, and several comorbidities, neo-adjuvant chemotherapy is a very reasonable choice, while a healthier younger patient with disease that appears resectable should be offered initial surgery with the goal to accomplish a complete tumor debulking with no visible residual disease.

Summary of Primary Debulking Surgery for Ovarian Cancer

Many factors contribute to how long a given patient with advanced ovarian cancer survives. Inherent genetic characteristics of the tumor may play a more important role in overall survival than stage or cytoreductive surgical debulking. However, the study of genetic factors in relation to surgical treatment is in its infancy. At present, the degree of surgical debulking is the only prognostic factor that can be influenced by the surgeon, and we know that among patients with advanced-stage III/IV ovarian cancer, a woman who has undergone a complete debulking has the most favorable prognosis. Whether a complete resection is performed is, at least in part, determined by the surgeon's skill and willingness to engage in a maximal surgical effort. Once the decision has been made to proceed, the goal of every surgery in patients with advanced-stage III/IV ovarian cancer should be a complete resection of all visible tumors.

However, ultraradical surgery, involving the addition of upper abdominal procedures to pelvic tumor debulking, will increase morbidity and not every patient is a good candidate for such an aggressive approach (178). Large-volume involvement of the upper abdomen, extended small and large bowel surface and mesentery involvement, and multiple liver metastases, will preclude an optimal debulking. Wright and colleagues, reviewing a

large administrative database with over 28,000 patients, showed that the complication rate of extensive ovarian cancer debulking increases with age. Women younger than 50 years, 70 to 80 years, and those older than 80 years have a 17.1%, 29.7%, and 31.5%, complication rate respectively (178).

Two groups of factors will contribute to the decision to take a patient to surgery and perform a radical debulking procedure (146): (a) A careful preoperative evaluation of patient-related risk factors: Patients with significant comorbidities and low performance status (American Society of Anesthesiology [ASA] preoperative scores 3 or 4, poor nutritional status, low albumin < 3 g/dL) have a low likelihood of optimal debulking to microscopic disease and are at risk of significant peri- and postoperative morbidity; (b) A critical evaluation of the extent of disease with particular attention to upper abdominal tumor burden, ascites, and upper abdominal tumor distribution. Patients with 1 or more of these risk factors often have a prolonged postoperative recovery, since they have limited ability to withstand a long operation. Furthermore, once a complication occurs, the patient may not receive chemotherapy, and is more likely to succumb to disease within 3-months (146,179). For these patients, neo-adjuvant chemotherapy is a well-studied alternative to a debulking surgery that has a similar outcome (Fig. 24.18) and less morbidity (152). Sometimes it is not possible to preoperatively decide if radical debulking surgery is feasible because of the limited ability of CT scans to predict success (144). In these difficult cases a laparoscopy or mini-laparotomy will give a better impression of disease extent than any imaging modality, and should be performed with the plan to forego a more extensive surgery if extensive disease is found. In one small prospective study, a laparoscopic procedure was able to predict whether optimal debulking was possibly in 96% of patients (180).

In summary, the extent of surgical cytoreduction in patients with advanced ovarian cancer and multiple comorbidities should be determined for every patient individually. If in doubt, and until more data becomes available, it is reasonable to treat these patients with neo-adjuvant chemotherapy followed by

FIGURE 24.18. Neo-adjuvant chemotherapy versus upfront debulking.

debulking surgery. Surgical debulking is only one component of the treatment that women with ovarian cancer require.

Second-Look Surgery

Second-look laparotomy was often performed in the 1980s after primary surgery and adjuvant cisplatin-based therapy for prognostic information and as an effort to improve survival by continuing chemotherapy for those found to have residual small volume disease. Second-look surgery is no longer generally performed, because no therapy instituted as a result of disease found at second-look surgery was found to alter prognosis. Reoperation following chemotherapy also introduces unnecessary morbidity. About one-third of such patients with advanced ovarian cancer were free of disease at a second-look laparotomy, yet even after a negative second look, over half of these patients eventually recurred.

Interval Debulking for Suboptimally Debulked Patients

The term interval debulking surgery refers to a surgical procedure in a patient with persistent abdominal disease after an initial surgical debulking effort and 3 cycles of chemotherapy.

There is conflicting evidence from 2 large prospective, randomized trials whether secondary cytoreductive surgery can improve survival in these patients (181,182). In a multicenter trial conducted by the European Organization for Research and Treatment of Cancer (EORTC) (181), patients with suboptimal (>1 cm) disease remaining after primary cytoreduction were treated with 3 cycles of cyclophosphamide and cisplatin. Those without progression were randomized to interval debulking surgery and additional chemotherapy *versus* additional chemotherapy alone. With approximately 140 patients randomized to each arm, patients undergoing the interval debulking showed a statistically significant improvement in both progression-free interval and median survival (Fig. 24.19A). The survival of patients with residual lesions of more than 1 cm after the interval debulking surgery was similar to that of patients who did not undergo the surgery.

The GOG has reported the results of a prospective, randomized trial of interval secondary cytoreduction in patients with advanced FIGO stage III/IV ovarian cancer with suboptimal (> 1 cm) residual disease (GOG#152) (182). Five hundred fifty patients were enrolled in this study within 6 weeks of initial surgery. After 3 cycles of paclitaxel and cisplatin, patients without evidence of tumor progression were randomized to receive either secondary cytoreduction and 3 additional cycles of chemotherapy or chemotherapy alone. At the time of the report (2004), median PFS and OS (Fig. 24.19B) for the interval cytoreduction group were 10.5 months and 33.9 months, respectively, compared to 10.7 months and 33.7 months for the chemotherapy-alone group. A consistent lack of effect was seen in all patients independent of the residual tumor size at the end of the interval debulking surgery.

Several theories have been advanced to explain the difference in outcomes between the GOG and European studies, both large prospective, randomized trials. In the GOG trials, both the initial and interval cytoreductive operations were clearly defined and were performed almost exclusively by trained gynecologic oncologists, whereas in the EORTC trial the extent of the initial surgery was not clearly defined and surgery was most often performed by general gynecologists. As a result, residual disease following primary surgery measured less than 5 cm in about two-thirds of the GOG patients, compared to one-third of the patients in the EORTC trial. Following chemotherapy, residual disease greater than 1 cm was found in 56% of the GOG patients *versus* 65% of the European patients. This resulted in a higher likelihood of

successful cytoreduction in the EORTC trial, with conversion from suboptimal to optimal residual tumor in 45% of patients as compared to 36% in the GOG trial.

Additionally, the chemotherapeutic regimen used in the GOG trial, paclitaxel and platinum, may have reduced the benefit of interval cytoreduction relative to the EORTC trial, which used a platinum and cyclophosphamide combination. Differences in outcome may also be related to differing posttreatment surveillance and to the availability of more effective second-line therapies since the EORTC trial completed accrual in May 1993. It is of interest to note that the similar median and overall survival in both arms of the GOG trial were substantially longer than those reported in the best (interval cytoreduction) arm of the EORTC trial.

In conclusion, it is probable that patients who had an initial maximal effort at cytoreduction resulting in suboptimal

debulking will not benefit from interval cytoreduction (182). Selected patients who previously only had a biopsy, removal of the ovary, or partial removal of ovarian tumors will benefit from one attempt at maximally debulking advanced ovarian cancer (181).

Secondary Cytoreductive Surgery for Recurrent Disease

Despite improvements in adjuvant chemotherapy for ovarian cancer (intraperitoneal chemotherapy [183], dose-intense chemotherapy [184], Bevacizumab [185]) and aggressive primary debulking (including upper abdominal procedures), the majority (70%) of patients with advanced epithelial ovarian cancer will have a recurrence (90). Since there is currently no chemotherapy that can cure recurrent ovarian cancer, surgical resection of recurrent disease is an option for a select group of patients.

An early retrospective study of secondary cytoreduction for recurrent disease from investigators in Munich showed an overall survival time of 29 months for patients cytoreduced to microscopic residual disease, while patients with any visible disease had a median survival of only 9 months (186). Chi and colleagues reviewed the Memorial Sloan-Kettering experience of 157 patients who had undergone secondary cytoreduction (187). For patients with a disease-free interval from completion of their primary adjuvant chemotherapy between 6 to 12 months, 13 to 30 months, and longer than 30 months, the median survival rates were 30, 39, and 51 months, respectively ($p = 0.005$). Median survival was 60 months for patients with a single site of recurrence, while patients with carcinomatosis had a median survival of 28 months ($p < 0.001$). In patients whose residual disease at the completion of surgery was larger than 0.5 cm, the median survival was 27 months, compared to 56 months in patients with residual disease lesser than 0.5 cm. Based on this study, disease-free interval, number of sites of recurrence, and residual disease at the end of surgery are independent prognostic factors for OS in patients considered for secondary cytoreduction.

Eisenkop and colleagues prospectively followed patients who underwent secondary cytoreductive surgery, and showed that patients with microscopic residual disease had a median survival of 44.4 months compared to 19.3 months if any visible disease was left (188). Therefore, as is the case with primary cytoreductive surgery, the disease burden at the end of surgery seems to be the most important prognostic factor. The German/Swiss DESKTOP I trial (189) enrolled 267 patients with recurrent ovarian cancer who had secondary cytoreductive surgery and found that patients with carcinomatosis had a 19.9 months median survival *versus* 45.3 months for patients without disseminated disease ($p < 0.0001$). In this trial, a score ("AGO score") was developed to predict optimal operability in this recurrent patient group, using criteria that includes performance status, complete debulking at first surgery, and less than 500 cc of ascites. The score was then tested in the DESKTOP II prospectively: 76% of the patients who fulfilled all 3 criteria had an optimal debulking (190). Another study, however, should serve to caution against too much surgical enthusiasm. Güngör (191) reviewing patients with recurrent ovarian cancer after optimal debulking and with a disease-free interval greater than 6 months showed that patients who had suboptimal secondary cytoreduction surgery had a worse prognosis when compared to a nonsurgery group who only underwent chemotherapy.

A small subset of patients (4% to 5%) will present with isolated recurrences in retroperitoneal lymph nodes. Several small retrospective studies found that complete resection of lymph nodes limited to one anatomic region (60% are high paraaortic) is associated with significantly improved survival (165,166). If this is the only site of disease, postoperative radiation of the lymph node bed might reduce the risk of recurrence.

All studies reporting on secondary cytoreductive surgery are retrospective or prospective nonrandomized studies, which have an inherent bias for the selection of patients in a favorable prognostic group to receive surgery. However, based on the consistent findings of these studies the following selection criteria for secondary debulking seem reasonable: Patients with (a) a disease-free interval longer than 12 months, (b) platinum sensitive disease with additional chemotherapy options, (c) oligometastatic or localized disease with the absence of ascites and carcinomatosis, and (d) a good performance status (192). For all other patients, the potential morbidity and limited benefit associated with suboptimal secondary cytoreduction should be carefully weighed against the possible benefit of surgery. In cases where radiologic studies do not provide a clear preoperative picture of disease extent a diagnostic laparoscopy to assess resectability might assist with the decision (180). In appropriately selected patients secondary cytoreduction is associated with an improved patient outcome with the largest benefit in patients from whom all visible disease could be removed.

Two prospective randomized trials will hopefully clarify the impact of secondary cytoreductive surgery on survival. The DESKTOP III trial and the GOG #213 trial both randomize patients with platinum-sensitive disease to secondary cytoreduction or no surgery with chemotherapy required in the GOG trial and recommended in the DESKTOP III trial.

Palliative Surgery Including Surgery for Malignant Bowel Obstruction

The primary goal of palliative surgery is to relieve symptoms and improve the quality of life, rather than prolonging survival. Bowel obstruction is one of the main causes of death from ovarian cancer. Others are extensive ascites, intractable pleural effusions, sepsis from a bowel perforation, and tumor cachexia (193).

In patients with ovarian cancer, a malignant bowel obstruction is the most common reason for a hospital admission during the last year of life. The median survival of patients admitted with a bowel obstruction is around 3 months. The tumor, while it does not deeply invade the bowel, connects and then kinks bowel loops and/or encases the bowel mesentery, limiting bowel mobility, blood supply, and causing a combination of mechanic bowel obstruction and adynamic ileus. Other etiologies can be extrinsic compression of the bowel lumen by intra-abdominal tumors or retroperitoneal lymph nodes pushing on the pyloric antrum or the duodenum. In patients without evidence of disease recurrence and who underwent an extensive debulking procedure or received postoperative radiation, adhesions, an old hematoma or a new incisional hernia may be the cause of a bowel obstruction.

Patients with advanced disease tend to present to the emergency room with one of the following signs and symptoms: tachypnea/dyspnea because of cranial displacement of the diaphragm/atelectasis of lower lung lobes or a pleural effusion, tachycardia from dehydration and pain, a low-grade fever from the dehydration and the chronic inflammation associated with a long-standing obstruction. Symptoms of a bowel obstruction include nausea and vomiting, periumbilical cramping and a combination of dull and sharp abdominal pain, and abdominal distension.

Instant nausea and vomiting after oral intake or projectile vomiting, is an indication of a very proximal obstruction of the stomach or duodenum which cannot not be relieved by surgery. If the patient has an adynamic ileus from carcinomatosis the auscultation will show absence of bowel sounds, yet if there is a complete small bowel obstruction bowel sounds will be high pitched. The proximal bowel obstruction might be caused either by an extensive upper abdominal tumor load or by enlarged

high paraaortic lymph nodes causing extrinsic compression of the duodenum or jejunum. The abdomen of patients with a proximal bowel obstruction is often not distended, which can give the mistaken impression of a limited problem. Laboratory analysis often shows hemoconcentration, low albumin, and a hypokalemic, hypochloremic metabolic alkalosis, which is sign of repeated vomiting or longstanding NG tube drainage. Patients with a volvulus or chronic bowel ischemia may have a metabolic acidosis, leukocytosis, and increase in lactate. While bowel obstruction is really a clinical diagnosis, an upright abdominal x-ray will show air fluid levels. A contrast CT scan of the abdomen and pelvis or a small bowel follow-through will allow for the evaluation of the small/large bowel over its entire length and will help determine whether a patient has multiple, partial, or complete bowel obstructions, or if there is a single transition point. The bowel is often dilated proximal to the transition point and collapsed after the transition.

Treatment options at this point include palliative care with symptom control, a percutaneous endoscopic gastrostomy (PEG) tube, parenteral nutrition, palliative chemotherapy, and palliative surgery. Initial treatment for a malignant bowel obstruction should be conservative and may include bowel rest and hydration to correct metabolic abnormalities, which are signs of a longstanding obstruction. Additional supportive measures are treatment with octreotide to reduce secretions, antiemetics, corticosteroids to reduce inflammation and as an antiemetic, and adequate pain management that will require narcotics.

In selected patients it is possible to accomplish a temporary surgical correction and relieve the blockage by either removing tumors obstructing the bowel or by performing a diversion that may be a colostomy, ileostomy, or a limited bowel resection with intestinal bypass. Preoperative contraindications to an attempted surgical correction of a malignant bowel obstruction include an adynamic ileus caused by carcinomatosis or extensive ascites, diffusely metastatic cancer with bowel obstructions on multiple levels, and involvement of the proximal ileum, duodenum or stomach. Relative contraindications to palliative surgery for a malignant bowel obstruction are a long-standing obstruction, significant deconditioning and tumor cachexia (low serum albumin), multiple previous abdominal surgeries, and rapidly progressing, chemotherapy resistant disease. A very proximal obstruction of the stomach or duodenum can rarely be relieved by surgery.

Since the purpose of palliative surgery is to improve the quality of life, the procedure must be short and limited, with the lowest possible complication rate. In experienced hands and with appropriately selected patients, a surgical correction is possible in 84% of all patients and successful palliation, defined as the ability to tolerate oral intake for at least 60 days after surgery, in 71% of patients (194). In 16% of patients, a gastrostomy tube was placed and most of the other patients received an ileostomy, a colostomy, or the obstructed area was bypassed. The rate of major surgical complications was 22% and included enterocutaneous fistula formation, abscess formation, bacterial peritonitis, thromboembolic events, and death. The median survival for patients who were able to receive chemotherapy (70%) was 9.7 months, while it was 2.4 months for the other patients (194).

Excessive ascites production is also often encountered in patients with progressive disease. Ultrasound guided intraperitoneal catheter placement is safe and can be performed intermittently as an outpatient procedure. Visceral injury followed by peritonitis is very rare with this procedure, but with repeated paracentesis the ascites may become loculated and drainage incomplete. Often repeated paracenteses are necessary, and should this be the case, a permanent indwelling catheter can be placed in the patient's abdomen and the patient or her family instructed on how to drain the ascites. Potassium-sparing diuretics (Triamterene, Spironolactone) or anti-angiogenesis therapy (e.g. aflibercept) may also reduce ascites production. (558)

PATHOLOGY

Classification

The WHO classification of surface epithelial tumors is summarized in Table 24.9. Epithelial tumors comprise about half of all ovarian tumors, and account for 40% of benign tumors and 90% of malignant tumors. Over 1,200 consecutive ovarian surface epithelial tumors accessioned at the Washington Hospital Center from 1999 to 2011 were recently reviewed using uniform pathologic review with current criteria (Table 24.10). Although not population-based, these data on carcinomas are very similar to population-based data from Canada (195) and Sweden (196).

The apparent cell type distribution of ovarian cancer has changed significantly in the past 2 decades as metastatic mucinous carcinomas have been recognized and properly categorized (197). Primary invasive mucinous carcinoma now appears to be quite uncommon, comprising only 3% of ovarian carcinomas and less than 1% of advanced-stage carcinomas (Table 24.11). Carcinosarcoma (malignant mixed müllerian tumor), previously regarded as a rare primary ovarian tumor, now appears to comprise over 6% of ovarian carcinomas in the United States. This apparent increase in frequency may be due to more thorough sampling with the identification of small sarcomatous components in otherwise typical high-grade serous carcinomas.

Abbreviations used in this section

AGUS	Atypical glandular cells of undetermined significance
APCCT	Atypical proliferative clear cell tumor
APET	Atypical proliferative endometrioid tumor
APMT	Atypical proliferative mucinous tumor
APST	Atypical proliferative serous tumor
DPAM	Disseminated peritoneal adenomucinosis
ESS	Endometrioid stromal sarcoma
MMMT	Malignant mixed mesodermal tumor
MPSC	Micropapillary serous carcinoma
MBT	Mucinous borderline tumor
PMP	Pseudomyxoma peritonei
SBT	Serous borderline tumor
STIC	Serous tubal intraepithelial carcinoma
TCC	Transitional cell carcinoma

Pathogenesis

Dualistic Model of Ovarian Cancer Pathogenesis

Advances in molecular biology correlated with morphologic studies have shed new light on the pathogenesis of ovarian carcinoma and have challenged many of the time-honored concepts of ovarian neoplasia. These studies have led to the proposal of a new model of carcinogenesis (198). Concomitantly, recent studies have provided evidence that the origin of ovarian carcinoma, previously regarded to be the ovarian surface epithelium, may be the fallopian tube in many or possibly even most cases (199,200). The view that ovarian cancer begins in the ovary and spreads systematically to the pelvis, abdomen and then distant sites is now less favored and the concept that ovarian carcinoma, over time, progresses from well to poorly differentiated also appears to be incorrect for the vast majority of cases.

Accumulating clinicopathologic and molecular genetic data have led to the proposal of a new model of ovarian

Type I and Type II, based on their clinicopathologic features and characteristic molecular genetic changes (198).

Type I tumors are low-grade, relatively indolent neoplasms that arise from well-characterized precursor lesions (atypical proliferative [borderline] tumors and endometriosis) and usually present as large stage I neoplasms. This group includes low-grade serous (invasive micropapillary serous carcinoma [MPSC]), low-grade endometrioid, mucinous, and probably clear cell carcinomas. Clear cell carcinoma, although it exhibits most of the features of the Type I tumors such as association with a well-established precursor (endometriosis) and frequent large size and presentation in stage I, is typically high-grade unlike the other Type I tumors. Nonetheless, preliminary molecular genetic data show a greater similarity of clear cell carcinoma to Type I as compared to Type II tumors.

Type I tumors often harbor mutations of genes encoding protein kinases including *KRAS*, *BRAF*, *PIK3CA*, and *ERBB2*, as well as other signaling molecules including *PTEN* and *CTNNB1* (β -catenin). The atypical proliferative or borderline serous and mucinous tumors appear to develop from cystadenomas, while the atypical proliferative endometrioid and clear cell tumors arise from endometriosis. Type I carcinomas are heterogeneous and often display areas identical to their benign and atypical proliferative counterparts. Similar mutations have been identified in the different components of each tumor cell type, providing supportive evidence of the neoplastic sequence of benign to atypical proliferative to invasive carcinoma.

In contrast, Type II tumors, of which the vast majority are high-grade serous carcinomas and its variants, are aggressive, high-grade neoplasms from the outset; in the past they have been said to arise “de novo.” Recent data suggest that high-grade serous carcinomas arise from intraepithelial carcinomas, the majority of which have been detected in the tubal mucosa, usually the fimbriae (serous tubal intraepithelial carcinoma, or STIC). It is currently not clear what proportion of high-grade serous carcinomas arise from the tube. A large majority of Type II carcinomas have *TP53* mutations. *TP53* mutations have been found in tubal intraepithelial carcinomas and in a recently described putative precursor lesion of tubal intraepithelial carcinoma designated “p53 signature”. This latter lesion appears

morphologically normal but overexpresses p53 and can harbor a p53 mutation. These findings highlight the importance of p53 mutation in the early development of high-grade serous carcinoma (198,201). The dualistic model is supported by findings from many investigators (202).

The anatomical progression of ovarian carcinoma is poorly understood. It is generally assumed that carcinoma originates in the ovary, is confined to the ovary for a period of time and then disseminates to the pelvis, followed by the abdominal cavity before spreading to distant sites. This view underlies the basis of the FIGO staging system (see Table 24.6) in which, tumors confined to the ovary are stage I, those involving the pelvic organs stage II, with involvement of abdominal organs stage III, and distant sites stage IV. This view also has been used to justify the attempts to develop a screening test. There are, however, significant problems with this assumption. Clinicopathologic comparison of stage I with stage III carcinomas shows that stage I tumors are predominantly Type I and nonserous while stage III tumors are predominantly Type II and most often high-grade serous (203).

It is important to appreciate that Type II ovarian carcinomas account for the vast majority of ovarian cancer deaths (204). Most Type II tumors are high-grade serous carcinomas and at the time of diagnosis, most are widely disseminated throughout the peritoneum with the largest volume of tumor outside the ovaries. Serous carcinoma and its variants (peritoneal serous carcinoma, carcinosarcoma, undifferentiated carcinoma and mixed carcinomas with a high-grade serous component) account for 87% of cases of peritoneal carcinomatosis from ovarian carcinoma (Table 24.11; 197) and accordingly the vast majority of ovarian cancer deaths. These data that analyze stage distribution by histologic type suggest that early and advanced-stage tumors are often fundamentally different diseases, and provide further support for the dualistic model (203).

Putative Histopathologic Precursor Lesions

The study of precursors of ovarian carcinoma is very difficult because the ovaries are not readily accessible for screening, and ovarian carcinomas typically present in advanced stage,

obliterating or rendering unrecognizable any possible precursor lesions. Furthermore, identification of a putative precursor lesion is based on microscopic examination of a complete oophorectomy specimen, and therefore the natural history of the lesion cannot be observed. Studies on ovaries removed prophylactically from high-risk women, and normal-appearing ovaries contralateral to stage I carcinomas, have generated conflicting data.

Surface Epithelial Dysplasia

Investigators have studied ovarian surface epithelium in the vicinity of carcinomas in an attempt to define the putative entity of “ovarian dysplasia,” and have reported atypical cellular and nuclear features that appear more frequently in ovarian surface epithelium near or contralateral to carcinomas in comparison to control ovaries. These findings, however, have not been widely corroborated.

Surface Epithelial Inclusions

The superficial ovarian cortex usually contains simple glands and cysts lined by a single layer of flat, cuboidal epithelium or ciliated tubal-type epithelium (Fig. 24.20). These are termed surface epithelial or cortical (formerly “germinal”) inclusions, and their presence directly correlates with age. Historically, they have been considered to arise after postovulatory repair of the damaged ovarian surface; however, the evidence for this is weak. It has been stated that they arise when invaginations or clefts of the ovarian cortex lined by surface epithelium lose their connection to the surface. However, this circumstantial observation may be based on confusion of tangentially sectioned clefts with inclusions (205). It has recently been suggested that the origin of inclusions could be the fimbrial epithelium, which is in close apposition with the ovarian surface epithelium (201). In this model, the postovulatory disruption of the ovarian surface allows fimbrial epithelium access to the superficial cortical stroma. At present, this is the most compelling hypothesis as it explains the tubal morphology of inclusions and their age distribution, but the evidence is largely circumstantial. Nonetheless, there is no more than circumstantial evidence for the previously “well-established” surface epithelial origin of these inclusions. Furthermore, the ovarian surface epithelium is not müllerian in origin; it is mesothelial, and metaplasia of the peritoneal mesothelium

Table 24.11 Distribution of 530 Invasive Ovarian Carcinomas by Cell Type, Washington Hospital Center, 1991 to 2011

	Stage I	Stage II	Stage III	Stage IV	Totals (%)

High-grade serous includes those of peritoneal and tubal origin. Transitional cell carcinomas (other than malignant Brenner tumors) are classified as high-grade serous carcinoma (see text).

FIGURE 24.20. Cortical inclusions are lined by ciliated columnar tubal-type epithelium within the ovarian cortical stroma. The ovarian surface is seen at the top left.

to tubal-type epithelium, though widely believed to occur, is another widely held assumption that has not been convincingly demonstrated.

Some studies on prophylactic oophorectomy specimens in high-risk women and normal-appearing ovaries contralateral to stage I carcinomas have shown a higher number of these cortical inclusions in comparison to controls, but others have not confirmed these findings. These studies have also evaluated a variety of other features including cortical invaginations (clefts) and surface papillomatosis and some have found the latter 2 to be more common in cancer-prone ovaries than in controls, but these findings have not been confirmed by other investigators either. Many of these studies have significant drawbacks. For example, the method of quantitation of cortical inclusions and clefts is variable among studies (206).

Endometriosis

Although the precursors of ovarian carcinoma are for the most part unknown, endometriosis is a well-documented and easily recognized precursor lesion. This is because carcinomas arising in endometriosis are Type I tumors, grow slowly, and therefore allow a greater window of opportunity for discovery prior to obliteration of the precursor lesion by the carcinoma. Endometriosis is common and found in about 10% of reproductive-age women, but the risk of malignant transformation in an individual patient is very low. Nonetheless, endometriosis is associated with up to about 20% of ovarian cancers and is acknowledged to be the precursor of many endometrioid and clear cell carcinomas and an occasional mucinous carcinoma. Serous carcinomas may be found coincidentally in women with endometriosis but do not appear to be histogenetically related.

The plausibility of endometriosis as an ovarian cancer precursor is supported by our understanding of endometrial cancer precursors. Atypical endometrial hyperplasia in the uterus is a well-defined precursor of endometrial adenocarcinoma, and changes similar to this lesion are occasionally observed in endometriosis. In addition, atypical changes are also seen in endometriosis in the vicinity of endometrioid adenocarcinomas of the ovary and even more frequently in association with clear cell carcinoma. On occasion, the full morphologic spectrum from endometriosis with hyperplasia, to atypical hyperplasia and well-differentiated endometrioid adenocarcinoma can be observed. Further support for the premalignant potential of endometriosis comes from molecular biologic studies, which have demonstrated molecular alterations including LOH in the *PTEN* gene and microsatellite instability, as well as chromosomal aberrations including trisomies and monosomies, all indicative of a neoplastic process.

It has been estimated that carcinoma develops in 0.3% to 3% of cases of endometriosis, but this is likely an overestimate since a large number of cases of endometriosis never come to biopsy. The true figure is probably closer to 0.3%. Ovarian endometriosis appears to be significantly more likely to undergo malignant transformation than extraovarian endometriosis (207).

Further evidence that endometriosis is a precursor of ovarian carcinoma is provided by large studies from Sweden and Japan. In a Swedish study of over 20,000 women hospitalized with endometriosis, after a mean follow-up of 11.4 years, the relative risk of ovarian cancer in comparison to the control population was 1.9. Patients with a long-standing history of endometriosis (10 years or longer) had a relative risk of 4.2 (208). In a study in Japan of 6,398 women with endometriosis, the standardized incidence ratio was 9.0 after 17 years of follow-up, with a risk of 13.2 in women diagnosed after age 50 (209). In the latter study, the mean age at diagnosis of ovarian carcinoma was 51, a reflection of the significantly younger age of women with endometriosis-associated cancers.

Benign and Atypical Proliferative (Borderline) Neoplasms

Although the natural history of benign ovarian tumors cannot be observed since they must be completely removed for accurate diagnosis, the observation of morphologically benign areas within carcinomas, and recent molecular data, strongly suggest that atypical proliferative/borderline tumors are precursors of low-grade serous, endometrioid and mucinous carcinomas (Type I tumors in the dualistic model). Invasive low-grade serous carcinomas (invasive MPSC) usually display large areas of atypical proliferative serous tumor (APST), also known as serous borderline tumor (SBT). Similarly, atypical proliferative mucinous tumors (APMT), also known as mucinous borderline tumors (MBT), are heterogeneous and usually display large areas of mucinous cystadenoma and APMT as well as morphologically intermediate forms, which include mucinous cystadenoma with focal atypia, and APMT with intraepithelial carcinoma (210). The progression of APST to low-grade serous carcinoma and APMT to mucinous carcinoma is supported by similar molecular changes in the separate components of these neoplasms.

Tubal Intraepithelial Carcinoma

It has recently been proposed that the origin of some serous carcinomas is the tubal fimbriae (198,200). The fimbriae are normally in close contact with the ovarian surface. Reported associations of chronic salpingitis with both ovarian serous tumors and tubal carcinomas (31,211,212) suggest the possibility of incorporation of fimbrial epithelium into the ovarian cortex via adhesions or a role of salpingitis in tubal carcinogenesis (213).

The typical fallopian tube carcinoma is a high-grade serous carcinoma and, until recently, was felt to be characterized by a dilated tubal lumen with the tubal mucosa displaying grossly obvious papillary tumor. In fact, a luminal tumorous mass has generally been required to assign the primary site to the fallopian tube (214). However, a fimbrial carcinoma seems unlikely to cause luminal dilatation except possibly in a short distal segment, and could be misinterpreted as ovarian in origin, particularly because the fimbriae normally reside on the ovarian surface. Epithelial atypia, intraepithelial carcinoma (STIC) and small high-grade serous tubal carcinomas have been found in prophylactic specimens from women with *BRCA* mutations (214). In addition, it is frequently impossible to completely separate the ovary and tube for evaluation in serous carcinoma. All of these observations suggest the possibility that some apparent ovarian cancers are in fact tubal in origin (198,200). Carcinoma involving the tubal mucosa has generally been regarded as secondary when there is also tumor in the ovary, peritoneum and/or endometrium, however this is an assumption. Many of the dominant tumorous adnexal masses appear to be paraovarian and/or extensively involve the fallopian tube in a manner consistent with peritoneal or tubal origin. The identification of *TP53* mutations in STICs as well as in high-grade serous carcinomas provide further support for the tubal origin of many high-grade serous carcinomas.

Meticulous examination of risk-reducing salpingo-oophorectomy (RRSO) specimens has disclosed occult invasive carcinomas in 3% of cases: 53% ovarian, 39% tubal, and 8% peritoneal (205), and it has been suggested that some apparent primary peritoneal carcinomas after RRSO reflect undetected microscopic ovarian carcinomas. It has also been suggested that some apparent peritoneal carcinomas in women who have undergone oophorectomy but not salpingectomy may reflect metastases from primary tubal carcinomas. Foci of STIC and atypical hyperplasia have been reported in RRSO specimens and the tubal fimbria is by far the most common site (78,79,85,200,215,216,217). As noted earlier, the reported frequency of occult invasive carcinomas in prophylactic specimens from high-risk women is 3% but varies widely; 0% to 12% in a compilation of 16 series, which

included 1,750 patients (205). In an additional 1%, STIC has been identified, making intraepithelial or invasive tubal carcinoma the majority of occult carcinomas. The wide range among studies could reflect differing thresholds for the diagnosis of tubal carcinoma, particularly intraepithelial carcinoma. In addition, there are several potential sources of bias in these types of studies (218). The interobserver reproducibility of the diagnosis of STIC has not been optimal, but recent data suggest that using p53 and Ki67 immunostaining in conjunction with morphology markedly improves reproducibility (219).

STICs have been identified in association with a high proportion of high-grade serous carcinomas. STICs contain *TP53* mutations and are cytologically malignant but are confined to the tubal epithelium. More recently, it has been found that there are small foci of morphologically normal tubal epithelium that are immunohistochemically positive for p53, and that have a Ki-67 proliferation index higher than normal tubal epithelium but lower than that found in STICs. A minimum of 12 tubal secretory epithelial cells that are p53 positive has been proposed as a definition for a “p53 signature” that is a candidate for a STIC precursor (220). Such p53 signatures have been associated with STICs as well as apparent ovarian serous carcinoma, but are also not uncommonly found in the general population. *TP53* mutations have been found in a majority of p53 signatures. These findings have led to the proposal that the p53 signature is the long sought precursor of a subset of ovarian high-grade serous carcinomas. Much of these data derives from Crum and associates (220) and awaits confirmation in larger series and by other investigators.

In and around the fimbriae, there is a junction between the tubal epithelium and the mesothelium which has been designated the tubal-peritoneal junction (Figs. 24.21 and 24.22). This is an extensive and highly tortuous zone and had escaped notice until a recent comprehensive characterization (221). Because junctions between different types of epithelium, such as the gastroesophageal junction and the cervical transformation zone, are often hot spots for carcinogenesis, this region is now of great interest. We have often observed STIC within 1 to 2 mm of this junction, and on occasion STIC can be found precisely at this junction. Further characterization of the relationship of STIC to the tubal-peritoneal junction will be of great interest.

Intraoperative Consultation (Frozen Section)

Getting the most out of a frozen section requires open lines of communication between the surgeon and the pathologist. The value of clinical information and operative findings to the pathologist should not be underestimated. A frozen section should be requested only when information is needed to determine what surgical procedure will be performed. Unnecessary frozen sections waste valuable resources and introduce opportunities for error (222).

The main purpose of intraoperative consultation for an ovarian mass is to determine whether a malignancy is present so that staging can proceed. However, a simple diagnosis of “malignant” is not enough since metastatic neoplasms to the ovary are not infrequent and may present prior to the diagnosis of the primary lesion. Because 5% to 10% of malignant ovarian masses are metastases from extraovarian primaries, the pathologist should attempt to make as specific a diagnosis as can reasonably be rendered given the limitations of frozen section. The benign versus malignant distinction in most cases is easily made, and the accuracy in most hospitals is over 95% (223). More difficult and hence less accurate is the distinction of a primary from a metastatic tumor, and atypical proliferative/borderline tumor from invasive carcinoma, both of which will affect the surgical approach.

Atypical proliferative (borderline) tumors present a unique intraoperative problem. Low-grade serous neoplasms are heterogeneous, and low-grade serous carcinomas nearly always have benign appearing areas resembling a cystadenoma or an APST/SBT. The amount of tissue that can be examined intraoperatively is limited. Consequently, approximately 20% to 30% of ovarian tumors diagnosed as atypical proliferative (“borderline”) at the time of frozen section examination prove to be carcinomas on further sampling. Accordingly, it is important that the surgeon perform a thorough exploration when the frozen section is diagnosed as an APST/SBT. Whether a complete staging with its attendant morbidity should be undertaken depends on the findings at exploration, the level of suspicion for carcinoma on the part of both the pathologist and surgeon, and the patient’s preferences (222). Also of note is that the distinction of benign from atypical proliferative/borderline is not always reliable, with a tendency to overdiagnose borderline tumors intraoperatively (223). The likelihood of a tumor interpreted as borderline at frozen section proving to be a carcinoma increases with tumor size. One recent study showed that invasion was

found in 22.4% of tumors interpreted as borderline that were larger than 8 cm as compared to 3.2% of smaller tumors (224).

Discrepancy rates for frozen sections of ovarian mucinous tumors can exceed 1 in 3 (225). When a mucinous tumor is diagnosed intraoperatively, it is important for the surgeon to do a complete abdominal exploration. The likelihood of a mucinous tumor being an extraovarian primary increases with the degree of atypia, gross and microscopic complexity, and the presence of extraovarian disease. Simple unilocular mucinous cysts or cystadenomas are nearly always benign primary ovarian tumors. Once any degree of atypia is present, even if mild, an extraovarian primary should be considered in addition to a primary ovarian APMT/MBT. If peritoneal disease in the form of pseudomyxoma peritonei (see pseudomyxoma peritonei later in this chapter) or metastatic adenocarcinoma is present, the likelihood of an extraovarian primary is very high, as most true primary ovarian mucinous carcinomas are stage I. If clear-cut evidence of mucinous carcinoma is present within the ovary, the likelihood of an extraovarian primary is about 80%. This latter figure can be refined based on other findings including bilateral ovarian involvement, which is nearly always metastatic, or unilateral involvement with tumor size smaller than 10 to 13 cm, which is usually but not always metastatic (226). Nearly all primary ovarian mucinous carcinomas are large and unilateral. One study on the accuracy of frozen sections for ovarian mucinous tumors showed that a tumor size of greater than 13 cm was associated with a significantly increased discrepancy rate (227).

When an extraovarian primary is considered likely, the surgeon should perform a complete abdominal exploration with particular attention to the gastrointestinal and hepatobiliary tracts and pancreas, as most metastatic mucinous carcinomas to the ovaries arise in these sites. The appendix should be removed even if it appears normal, as small appendiceal neoplasms can disseminate, and appendectomy is a low-risk procedure.

CAP Checklist Reporting

The College of American Pathologists (CAP) has issued guidelines for the reporting of ovarian cancer (228). Complete reporting with the CAP cancer checklist requires assessment of ovarian surface involvement and tumor rupture for stage I and II disease. It is therefore important that the pathologist communicate with the surgeon or review the operative report to provide these data. For advanced-stage disease, the size of the largest peritoneal nodule needs to be assessed, and although this is often evident from the gross pathologic examination, input from the surgeon may be required since the tumor may be incompletely resected. In apparent stage III disease, clinical or pathologic information may be needed to determine whether distant metastases have been diagnosed (stage IV). Required elements of the checklist include specimen type, procedure, specimen integrity, primary site, tumor size, histologic type, grade and TNM stage.

Cytopathology

There are 2 types of cytopathologic specimens typically used in evaluation of ovarian epithelial neoplasms: fine-needle aspirates (FNA) of ovarian cysts and peritoneal fluids (obtained by peritoneal washing or by aspiration of ascitic fluid). FNA specimens or effusions from sites of distant metastasis may also be examined. Rarely, the presence of psammoma bodies in a Pap smear will be the first sign of primary or recurrent ovarian or peritoneal serous carcinoma, more commonly when associated with atypical glandular cells of undetermined significance (AGUS) or in older women with symptoms and signs suggesting malignancy. In a review of over 200,000 Pap smears, psammoma

bodies were found in 6 patients, 2 of whom proved to have ovarian carcinoma. In a review of 138 cases of AGUS, 5 (3.6%) proved to have ovarian cancers (229).

FNA may be useful in patients who appear to have inoperable ovarian cancer or who cannot undergo surgery for other reasons. Unsatisfactory specimens from ovarian cyst aspirates are common and limit the usefulness of the procedure. FNA specimens from most ovarian carcinomas are cellular and contain cytologically malignant cells, but accurate subclassification is often difficult and may be impossible based solely on cytologic material.

Cytologic samples of peritoneal fluid and diaphragmatic scrapings are routinely obtained during staging procedures for ovarian cancer. Cytologic findings are important in substaging early (FIGO I and II) ovarian cancer; malignant cells in peritoneal washings or ascites warrants assignment of tumors to stage IC or IIC. Malignant cells are more often present in ascites than in washings, and their presence correlates positively with volume of ascites, serous histology, stage and positive lymph nodes (230). The cytologic features of tumor cells generally resemble those in FNA specimens but may be more degenerate.

Peritoneal lavage is often performed at the time of RRSO in high-risk women. Occult carcinomas can be identified in these cytology specimens. Colgan and associates found malignant cells in 3 of 35 such specimens in the absence of other evidence of malignancy. Endosalpingiosis, manifested by morphologically benign tubal-type epithelium, was found in 22% (231). In 2 studies, malignant cells reported in washings at RRSO led to the discovery of early-stage tubal carcinomas (216,232).

Atypical epithelial cells resembling the ovarian tumor can occasionally be found in peritoneal cytology specimens associated with atypical proliferative (borderline) tumors. This finding has not been associated with adverse outcome and can be ignored except in the small proportion of patients who have bona fide carcinomas (patients with invasive MPSCs or APSTs with invasive implants), who can be substaged based on the presence or absence of epithelial cells resembling the primary ovarian tumor in the cytology specimens. This situation is rarely encountered since most MPSCs or APSTs with invasive implants are stage III.

Endometriosis and endosalpingiosis involving peritoneal surfaces may shed epithelial fragments into peritoneal washings or ascites. In addition, benign fallopian tube epithelium (particularly if salpingitis is present) and benign eutopic endometrial tissue may also be shed into the fluid via expulsion through the fallopian tubes. If the cells in the fluid are not obviously malignant, comparison of the cytologic features of the epithelium in the fluid with those of the tissue sections is essential. It is also important to note that cytologic abnormalities mimicking malignancy may be caused by chemotherapy as well as radiation.

Borderline Tumors

The borderline category of ovarian epithelial tumors was introduced in the early 1970s in order to describe a group of tumors that did not display invasion, but that occasionally appeared to behave in a malignant fashion. Their behavior appeared to be intermediate between benign cystadenomas and frank serous carcinomas. The classification was intended as provisional, but with its continued use over the past 3 decades, the borderline category has become entrenched. Recent studies have documented a wide histologic spectrum encompassed by the borderline category, which correlates with behavior. Some experts believe that the borderline group has been sufficiently resolved into benign and malignant types such that the category is no longer needed. However, most prefer to retain the borderline category with some modifications in terminology.

Serous Borderline Tumors

Tumors at the lower end of the morphologic spectrum of proliferating serous tumors behave in a benign fashion and display a papillary architecture in which papillae have a hierarchical branching pattern. These tumors are termed APSTs or serous borderline tumors (SBT). Tumors at the upper end of the morphologic spectrum behave like low-grade carcinomas and display a more complex nonhierarchical branching pattern characterized by delicate micropapillae and are classified as “noninvasive micropapillary serous carcinomas” (MPSC). APSTs comprise about 50% of atypical proliferative (borderline) ovarian tumors of all histologic types (Table 24.10). The atypical proliferative terminology has been accepted as synonymous with “borderline” while “low malignant potential” is currently not favored by most experts (233).

The most confusing aspect of serous borderline tumors is their association with peritoneal implants in the absence of invasive disease. There are 2 types of so called “peritoneal implants”: noninvasive and invasive. It is now clear, however, that patients with noninvasive implants have a survival that approaches 100%, while those with invasive implants have a prognosis similar to that of patients with invasive low-grade serous carcinoma, with 5- and 10-year survival rates of approximately 70% and 40%, respectively (233). Invasive implants are therefore believed to represent metastatic low-grade serous carcinomas. The finding of invasive implants with APST is very unusual and warrants further sampling of the ovarian tumor to identify occult areas of MPSC or invasion. The nature of noninvasive implants is unclear and there are conflicting data as to whether they arise from the ovarian tumor or are independent peritoneal proliferations. In either case, the prognosis is excellent and no therapy is needed, although patients may develop complications due to adhesions.

Microinvasion and associated lymph node lesions are found in a minority of cases. Different types of such lesions have been described (see below), and although their origin and significance are not entirely clear, the survival with microinvasion and/or lymph node lesions in the absence of MPSC or invasive implants is virtually 100%.

To summarize, APST/SBT can now be subclassified into those for which survival is close to 100% and those with a malignant, though indolent, behavior. APST with or without microinvasion, with or without lymph node lesions, and with or without noninvasive implants, can, for practical purposes, be considered benign. MPSC and APST/SBT with invasive implants, in contrast, have recurrence and mortality rates similar to those of low-grade serous carcinoma. Many authorities prefer the term “micropapillary serous borderline tumor” over MPSC.

Nonserous Borderline Tumors

The vast majority of nonserous borderline tumors are of the mucinous type. Endometrioid, clear cell and transitional cell types are rare and have never been convincingly demonstrated to be anything but completely benign.

APMT/MBT are not associated with peritoneal implants, and, like APST/SBT, have virtually 100% survival. Microinvasion (less than 5 mm) is occasionally seen and is not an adverse prognostic factor (210). Intraepithelial carcinoma may also occur in APMTs and although this is usually benign, there are occasional reports of malignant behavior (234). Since mucinous tumors are usually very large, malignant behavior is generally regarded as a manifestation of occult undetected invasion. Aggressive behavior of APMTs in the older literature is virtually always confined to patients with pseudomyxoma peritonei (PMP), and it is now clear that nearly all cases of PMP are of gastrointestinal origin (see below).

Primary versus Metastatic Ovarian Carcinomas

Metastatic carcinomas involving the ovaries often have unusual and deceptive features. The ovarian metastases may be the first manifestation of malignancy and may be much larger than the associated primary tumor. They are often cystic and accordingly grossly mimic primary ovarian carcinomas. They occasionally present prior to the identification of the primary tumor. The most common and problematic type of carcinoma metastatic to the ovary is mucinous carcinoma. Metastatic carcinomas are typically bilateral, small (typically less than 10 to 12 cm), display ovarian surface and superficial cortical involvement, a nodular pattern of ovarian involvement, and a haphazard infiltrative pattern of stromal invasion. However, some metastatic carcinomas, especially mucinous carcinomas derived from the colorectum, pancreaticobiliary tract, appendix, and endocervix, can exhibit gross and microscopic features simulating a primary ovarian mucinous or endometrioid tumor. In particular, metastases can be large, unilateral, and multicystic and can display deceptive patterns of ovarian involvement. If these patterns are not recognized, these metastatic carcinomas can be misinterpreted as primary ovarian APMT with intraepithelial carcinoma or well-differentiated mucinous or endometrioid carcinoma. Not infrequently, some of these metastases display highly differentiated areas adjacent to invasive areas, simulating benign and APMT precursor lesions.

When mucinous carcinomas in the ovaries are rigorously classified based on refined criteria and awareness of deceptive patterns, metastatic mucinous carcinomas are much more commonly encountered than primary ovarian mucinous carcinomas. In general, the presence of a mucinous carcinoma in the ovary, particularly if extraovarian disease is present, should always prompt the pathologist and surgeon to consider the possibility of metastatic mucinous carcinoma. Immunohistochemical analysis can be useful for identifying some metastatic mucinous carcinomas that simulate primary ovarian mucinous tumors; however the value of currently available markers is limited due to overlapping immunoprofiles of primary tumors and certain metastases (see Metastatic mucinous carcinoma, later in this chapter). Clinical evaluation is usually required to exclude metastatic mucinous carcinoma in the ovary derived from a clinically occult extraovarian source. Many investigators find it a safe and useful practice to consider mucinous carcinoma in the ovary metastatic until proven otherwise (205).

Serous Tumors

Serous Cystadenoma and Adenofibroma

Benign serous tumors including cystadenomas, adenofibromas and cystadenofibromas are common and account for two-thirds of benign ovarian epithelial tumors and the majority of ovarian serous tumors. Benign serous tumors are equally distributed among unilocular cysts, multilocular cysts and cystadenofibromas. The vast majority of lesions classified as serous cystadenoma display a serous epithelial lining lacking proliferation, suggesting that this tumor is not neoplastic. In a recent study, only 7% of serous cystadenomas had greater than 1 mm of epithelial proliferation (235). In support of this concept is the finding of polyclonality in the epithelium of most serous cystadenomas (236). Furthermore, another study confirmed these findings and found genetic abnormalities in the stroma of serous cystadenofibromas (237). Accordingly, not only are most serous cystadenomas probably not true epithelial neoplasms, the epithelium reflecting cystically dilated inclusions, but also the stroma may be the only neoplastic component. Accordingly, and most surprisingly, these may in fact, turn out to be benign stromal tumors, a finding which will eventually lead to reassessment of the distribution of ovarian neoplasms and the place of serous cystadenomas, if any, in the neoplastic sequence.

Cystadenomas are lined by pseudostratified, tubal type epithelium, with the characteristic elongated (secretory cell) and rounded (ciliated cell) nuclei. A single layer of flattened to cuboidal cells with uniform basal nuclei is also common. Mitoses and atypia are generally absent. Psammoma bodies are present in the stroma in 15% of cystadenomas. There is a broad spectrum of epithelial proliferation in benign serous tumors, which is manifested by variation in the prominence and complexity of the papillae, from a simple, single layer and blunt papillae to focal epithelial stratification and detachment of cell clusters approaching the degree of proliferation seen in APST/SBT. Identification of these features in 10% of the tumor separates serous cystadenoma from APST/SBT. If these features are focal (<10%), a diagnosis of serous cystadenoma with focal atypia is used (233).

Atypical Proliferative Serous Tumor; Serous Borderline Tumor (SBT)

The conceptual issues regarding the borderline category are discussed earlier in this chapter.

Clinical and Operative Findings

The clinical features of patients with APSTs are similar to those for serous cystadenomas; the mean age at diagnosis is 42 years. The risk factors are similar to those for ovarian cancer with notable exceptions of a higher frequency of infertility and a lower frequency of *BRCA* mutations.

APST are bilateral in 37% of cases in the older literature; the recent Stanford series showed a 55% bilaterality rate (238). This difference probably reflects more diligent examination of normal-sized ovaries with the identification of small serous proliferations contralateral to obviously tumorous ovaries. Exophytic papillae reflecting ovarian surface involvement are common, and are more often found in patients who also have peritoneal implants. Tumors with an exophytic component are associated with implants in up to two-thirds of cases as compared to 10% to 20% of tumors that are completely intracystic.

Gross Findings

APSTs have fine, friable, and exuberant papillary projections in contrast to the smooth walled cysts of serous cystadenoma. Papillae are nearly always present on the internal surfaces of the cyst, and are present on the external surfaces in up to 70% of cases.

Peritoneal endosalpingiosis in patients with APST is grossly inconspicuous. Noninvasive desmoplastic implants are firm and fibrotic, and are covered by an inflammatory exudate in 20% of cases. Invasive implants (metastatic low-grade serous carcinoma) resemble typical serous carcinoma but are often less bulky and more calcified.

Thorough sampling of the primary tumor for histologic examination is needed to rule out invasion. Previous recommendations of 1 section per cm of maximum tumor diameter (233) will not identify invasion in a significant minority of cases in which invasion is actually present. Recent data suggest that at least 2 sections per cm are needed to confidently exclude invasion (239) (see below, Microinvasion).

Microscopic Findings

APSTs display extensive epithelial stratification, tufting (budding) and detachment of individual cells and cell clusters in addition to hierarchical branching with successively smaller papillae emanating from the larger, more centrally located papillae. Stratification and budding in at least 10% of the tumor warrants a diagnosis of APST (Fig. 24.23). Focal areas of fusion of the epithelial buds may create a Roman bridge or cribriform

FIGURE 24.23. Atypical proliferative serous tumor (serous borderline tumor) displaying a complex papillary pattern with detachment of atypical cell clusters at the tips of the papillae.

pattern. Similarly, foci of nonhierarchical branching with fine elongated micropapillae emanating directly from large central papillae are seen not infrequently. When cribriform and/or micropapillary patterns constitute either a 5 mm or greater confluent area, or 10% or greater proportion, the tumor warrants classification as noninvasive MPSC (see below). Ciliated cells resembling fallopian tube epithelium are present in about one-third of tumors. The nuclei of APSTs resemble those in cystadenomas but tend to display slightly more atypia. Nuclei tend to be ovoid or rounded and nucleoli may be prominent. Mitoses are not common. Psammoma bodies are present in up to half of APSTs.

Microinvasion

Two distinct types of lesions have been designated “microinvasion” in APSTs. In most published reports, the 2 types have not been specifically distinguished or correlated with outcome. The usual type of microinvasion (eosinophilic type) accounts for the vast majority of reported cases. It is characterized by isolated cells and small cell clusters with abundant eosinophilic cytoplasm that appear to be budding from the epithelium into the superficial stromal cores of the papillae (Fig. 24.24). The lesion must be smaller than 5 mm, and can be multiple. When carefully sought, 10% of reported APSTs contain microinvasion; however, microinvasion was specifically noted in only 1.3% of reported APSTs up to 1999 (240). More recent series suggest that microinvasion is quite common and may be found in 25% or more of APSTs (241).

The second type of microinvasion occurs less commonly and is characterized by a haphazard infiltrative pattern of small solid nests of cells and micropapillae, often surrounded by a clear space and associated with an identifiable stromal response. This second pattern of invasion closely resembles primary ovarian invasive low-grade serous carcinomas (invasive MPSC) as well as “invasive implants” and may be referred to as “microinvasive carcinoma,” because the evidence, albeit limited, indicates that it is a manifestation of true invasive carcinoma. To qualify as microinvasive carcinoma, the lesion must be smaller than 5 mm. Multiple foci are permitted.

Microinvasion has been associated with a higher frequency of bilaterality, exophytic growth and peritoneal implants. Recent evidence suggests that the identification of microinvasion or microinvasive carcinoma is a clue that further sampling might disclose more extensive invasion. A minimum of 2 sections per

FIGURE 24.24. Microinvasion in an atypical proliferative serous tumor: The individual cells in the center with abundant eosinophilic cytoplasm reflect the more common type of microinvasion. Two papillae at left and right center are surrounded by a clear space reflecting the less common type of microinvasion (“microinvasive carcinoma”).

cm of maximum tumor diameter are needed to maximize detection of occult invasion (239).

A review of 94 patients with microinvasion reported up to 1999, the vast majority of which were not associated with peritoneal implants, showed 100% survival (240). More recently, the Stanford group found that microinvasion was a significant predictor of survival on univariate but not multivariate analysis (242). Although more data are needed, from the standpoint of prognosis and management, microinvasion does not appear to have clinical relevance. Whether or not staging is needed for a woman with microinvasive carcinoma is unclear. There are no data at present suggesting that follow-up or any treatment will influence recurrence or survival.

Associated Peritoneal Lesions: Endosalpingiosis and “Implants”

APSTs are often associated with serous lesions involving the peritoneum. Endosalpingiosis, or benign glandular inclusions, are found in 40% of patients. At present, 40% of reported APSTs are associated with peritoneal implants in contrast to 25% in the pre-1980 literature (240). However, in population-based and hospital-based material, the figure is closer to 10% to 15%, indicating a significant referral bias to large specialized centers in favor of tumors with implants. In the Stanford series, 59% had implants (243). Among those with implants, about three-fourths were noninvasive and one-fourth were invasive.

Endosalpingiosis, or benign glandular inclusions, may involve the peritoneal surfaces in patients with or without benign or malignant serous ovarian tumors. These glands typically are lined by simple columnar epithelium, which displays tubal differentiation. The epithelium may display minor degrees of atypia and form simple papillary structures; psammoma bodies are often present and may persist after degeneration of the epithelium.

Among women with APSTs, 31% (78% of all patients with implants) have peritoneal epithelial lesions that display a degree of proliferation beyond that usually seen in endosalpingiosis, but that lack features of invasion. These have been designated “noninvasive implants” and have 2 morphological forms: epithelial and desmoplastic.

Noninvasive epithelial implants are papillary and resemble the ovarian APST to some extent (Fig. 24.25). The cores of the papillae have fibrovascular support, and the epithelial cells

FIGURE 24.25. Noninvasive epithelial peritoneal implant associated with atypical proliferative serous tumor/serous borderline tumor. The implant displays a papillary architecture with psammomatous calcification. Note there is no invasion of adjacent peritoneum at top right and bottom left.

resemble those in endosalpingiosis. Thus, mild atypia is often present, but mitoses are usually absent. Calcification in the form of psammoma bodies is common and frequently is extensive.

The desmoplastic noninvasive implant is a plaque-like thickening overlying peritoneal surfaces and may extend into the septae that separate omental lobules creating a low-power appearance that suggests invasion (Fig. 24.26). These implants display an exuberant fibroblastic proliferation in which gland-like or papillary structures lined by epithelial cells are present. Psammoma bodies are usually present. The epithelium typically shows minimal cytologic atypia (Fig. 24.26). The fibroblastic proliferation often has a granulation tissue-like appearance characterized by edematous fascicles of plump fibroblasts, often with interspersed small vascular channels. Mitotic figures are usually absent, and psammoma bodies are present in over 90% of cases. This type of implant can be very difficult to interpret for pathologists who may be unfamiliar with these lesions. The rarity of advanced-stage APST/SBT results in most general pathologists seeing fewer than 1 case per year of the desmoplastic noninvasive implant and therefore most pathologists do not have experience with these lesions. Since the invasiveness of the

FIGURE 24.26. Noninvasive desmoplastic peritoneal implant displays an abundant granulation tissue-like spindle cell stroma with rare scattered glands lined by minimally atypical epithelium.

FIGURE 24.27. Invasive low-grade serous carcinoma/invasive peritoneal implant, characterized by small papillae lined by epithelium with mild atypia and surrounded by clear spaces.

implant is the determinant of benign versus malignant behavior in these tumors (see below), expert pathology consultation should be obtained if there is doubt about the diagnosis.

Among patients with APST or noninvasive MPSC, 9% (22% of those with implants) have invasive implants. In a population-based study from Canada, 12% of stage III patients had invasive implants (244). About three-fourths of patients with invasive implants have noninvasive MPSC; the finding of invasive implants with APST is very unusual and warrants further sampling of the ovarian tumor to identify occult areas of MPSC or invasion.

The characteristic architectural feature of an invasive implant is a haphazard infiltrative growth pattern (Fig. 24.27). A confluent or cribriform glandular pattern may be present. An exophytic pattern is not uncommon and usually displays a micropapillary pattern. Typically, micropapillae are haphazardly arranged and small solid nests of cells embedded in fibrous stroma and surrounded by a clear space or cleft are present (Fig. 24.27) (245). Invasive implants often display only mild cytologic atypia, but occasionally atypia is moderate. If severe atypia is present, high-grade serous carcinoma should be diagnosed.

Invasive implants are rare, and bonafide invasive implants reflect peritoneal metastases of MPSCs (some with undetected occult invasion) or, less likely, independent primary peritoneal serous carcinomas. Since MPSCs are often exophytic, malignant cells can theoretically be shed from the surface of the tumor and implant on peritoneal surfaces even when the primary tumor is not invasive. Invasive implants are associated with a poor prognosis and are considered invasive carcinomas.

Lymph Nodes

Nodal endosalpingiosis, or benign glandular inclusions, are found in 45% of patients with APST/noninvasive MPSC in whom lymph nodes are examined, in comparison to about 10% of women who have nodes removed for other reasons. Up to 42% of these patients have nodes containing serous lesions with proliferative features beyond endosalpingiosis. There is a strong association with invasive peritoneal implants and micropapillary architecture. In the Stanford series, 42% of patients with APST and lymph node resection had lymph node lesions, but this is likely an overestimate due to consultation bias and may also be related to the higher frequency of node sampling in patients with peritoneal implants (246).

Proliferative serous lesions in lymph nodes have been reported in over 100 cases of APST. Although these lesions have been referred

to as “metastases,” it is preferable to refer to them as “associated serous lesions in lymph nodes” or “lymph node involvement” as they may or may not be related to the ovarian tumor.

Lymph node lesions apart from endosalpingiosis can be divided into 2 types. One is characterized by individual cells and clusters of cells with abundant eosinophilic cytoplasm in the sinuses, predominantly subcapsular sinuses. The nature of these cells is unclear. When associated with simple papillae with serous features, they correspond to “individual cells, cell clusters and simple papillae,” as described in the Stanford series (246).

The second type of lymph node lesion is characterized by glandular inclusions and papillary serous structures, usually within or just beneath the capsule of the lymph node, that resemble the ovarian APST. The majority of these papillary serous lesions are also associated with endosalpingiosis in the same lymph node. Cytologic atypia is mild or moderate and mitotic figures are rarely seen. The observation of papillary proliferations arising within endosalpingiosis, and the rare reports of APSTs and carcinomas arising within lymph nodes from endosalpingiosis, suggest an independent origin of this second type of lymph node lesion.

In the 2006 Stanford series, 8 of 31 patients (26%) with lymph node involvement had invasive peritoneal implants. Among 22 patients with follow-up, 4 were alive with disease and there were 2 deaths, one in a patient with indeterminate peritoneal implants (246).

Clinical Behavior

In 6 prospective randomized trials including 373 patients with SBTs followed for a mean of 6.7 years, the survival was 100% (240), and large studies, some population-based, in the United States, Korea and Sweden show a 10-year survival of 96% to 100% (247,248,249). The disease-specific survival rate of patients with SBTs (APSTs and noninvasive MPSCs) confined to the ovaries after a mean of approximately 6.7 years, based on over 2000 reported cases, exceeds 99.5%. Essentially none of the allegedly fatal cases have been shown to have been comprehensively staged or sufficiently sampled. If patients with invasive implants (carcinoma) or indeterminate implants are excluded, then the overall survival for patients with lymph node lesions other than endosalpingiosis is 98% to 99%. The survival for patients with microinvasion or microinvasive carcinoma unassociated with invasive implants is 100%.

The behavior of SBTs with extraovarian lesions is based on the type of implants that are present. In the older literature, survival for SBTs with peritoneal implants ranged from 70% to 90%. Now, after excluding noninvasive MPSCs, nontumor deaths and invasive peritoneal implants, it is clear that the survival rate of patients with APSTs with noninvasive implants approaches 100% after a mean follow-up of 7.4 years (240). Recurrences and deaths reported in the literature are poorly documented in the majority of cases. When carefully documented, most deaths are either treatment-related or are the result of complications from adhesions and bowel obstruction rather than carcinoma (250). A literature review of over 18,000 borderline tumors which included over 4000 SBTs with clinical follow-up, failed to identify a single well-documented case of an SBT with noninvasive peritoneal implants, whose primary ovarian tumor had been adequately sampled to exclude invasion (at that time, 1 section per cm of maximum tumor diameter), that had progressed to documented invasive carcinoma. Based on a literature review of 467 noninvasive serous tumors, which included both invasive and noninvasive implants, the survival rate for patients with invasive implants was 66% after a mean follow-up of 7.4 years, compared to 95% for patients with noninvasive implants ($p < 0.0001$) (240). The survival rate for patients with invasive implants is similar to that for patients with invasive low-grade (micropapillary) serous carcinoma (251).

Low-Grade Malignant Serous Tumors

Low-grade serous carcinoma; micropapillary serous carcinoma (MPSC), invasive and noninvasive types; micropapillary serous borderline tumor; psammocarcinoma.

Low-grade serous carcinoma is synonymous with invasive MPSC and is a distinctive invasive carcinoma that is currently believed to arise from APSTs (see Pathogenesis, earlier in this chapter). It is not simply a low-grade version of the usual serous carcinoma, as accumulating evidence strongly indicates that this is a distinctively different cell type of ovarian carcinoma. It therefore should not be lumped with high-grade serous carcinoma, the usual fatal type of ovarian cancer.

A characteristic micropapillary and cribriform pattern in SBTs has been associated with invasive implants and a worse prognosis than typical SBTs (205). Despite the lack of demonstrable invasion, these tumors behave like low-grade carcinomas in contrast to the other tumors in this group (APSTs) which had nearly 100% survival. It was therefore proposed that they be designated noninvasive micropapillary serous carcinomas. Others have preferred the term “micropapillary serous borderline tumor”.

Unfortunately, the term MPSC has been used for 2 morphologically distinct, albeit related, entities and this has caused some confusion. The noninvasive form of MPSC is a variant of serous borderline tumor. The invasive form of MPSC is classified as well-differentiated serous carcinoma. It is likely that noninvasive MPSC is a form of *in situ* or intraepithelial carcinoma.

Noninvasive MPSCs comprise 14% of SBTs in consultation-based material; 10% in stage I, and 19% in advanced stage. In a population-based study from Canada, Gilks et al. found that 26% of advanced-stage SBTs were noninvasive MPSC (252). Invasive MPSCs are quite uncommon and comprise only 5% of ovarian carcinomas and 7% of serous carcinomas (Table 24.11). Advanced-stage serous carcinomas are invasive MPSC in 6% to 9% of cases.

Clinical and Operative Findings

The mean age of patients with the noninvasive form of MPSC is 42 years, the invasive form, 45 years, and the psammomatous variant (psammocarcinoma), 54 years. For noninvasive MPSC, two-thirds are bilateral as compared to only one-third with APST. Half of patients are stage I and the remainder are stages II and III. For invasive MPSC, 80% to 90% are bilateral and 94% are advanced stage. Bilateral tumors and those with an exophytic component are more likely to be associated with advanced-stage disease.

Gross Findings

The mean tumor size for the noninvasive form is about 8 cm, and for the invasive form, about 11 cm. Surface involvement is present in 54% of cases. As these tumors are very well differentiated, they tend to have a more papillary and cystic gross appearance like APSTs, and little if any necrosis, in contrast to many typical high-grade serous carcinomas that often have solid areas and extensive necrosis. Bilaterality, exophytic growth, and peritoneal implants are more common with noninvasive MPSC as compared to APST (253,254).

Microscopic Findings

Noninvasive MPSC is a proliferating serous neoplasm, which displays a high degree of epithelial proliferation and complexity but is noninvasive. The tumor displays a characteristic pattern of papillary branching. The distal papillary branches are thin and delicate with minimal fibrovascular support, and emanate abruptly from thick, more centrally located papillae without intervening branches of successive intermediate sizes, unlike

FIGURE 24.28. Noninvasive micropapillary serous carcinoma/micropapillary serous borderline tumor displays a cribriform or complex glandular pattern without invasion of underlying stroma.

the hierarchical branching pattern of APSTs. When the papillae fuse, a cribriform pattern or a Roman bridge-like pattern results on the surfaces of the large papillae (Fig. 24.28). Both micropapillary and cribriform patterns may be present. A 5 mm in diameter area of a confluent micropapillary pattern or 10% of the tumor occupied by the micropapillary pattern is required for the diagnosis. The majority of noninvasive MPSCs have areas of typical APST, in contrast to only 2% of high-grade serous carcinoma. In cases associated with metastases (invasive implants), invasion has been found in the primary tumor after exhaustive histologic sampling (239).

Noninvasive MPSC displays no invasion of the stromal cores of the papillae. Invasion in MPSC is recognized by haphazard infiltrative growth composed of solid nests or complex gland-like structures displaying micropapillae (Fig. 24.27). The nests and gland-like structures are often surrounded by a clear space or cleft. Psammoma bodies are common. The psammomatous variant of invasive MPSC, so-called “psammocarcinoma,” is characterized by a myriad of psammoma bodies occupying greater than 75% of the papillae.

MPSCs with or without invasion display similar cytologic features. Cells tend to be rounded with scant cytoplasm, and there is mild or moderate nuclear atypia, often with prominent small nucleoli. The cells in APSTs tend to be columnar, are often ciliated, and have less nuclear atypia. Mitotic activity tends to be low. Severe nuclear atypia warrants a designation of high-grade serous carcinoma even in the absence of overt invasion. In this latter situation, which is quite uncommon, further histological sampling of the tumor is likely to identify invasion.

The peritoneal implants associated with MPSC are frequently invasive (i.e., carcinoma). Among 157 reported cases of advanced-stage noninvasive MPSC, 45% of the implants were invasive, in comparison to 7% of the implants associated with APSTs ($p < 0.0001$). Noninvasive MPSCs also are more likely to be associated with serous lesions in lymph nodes that replace the node parenchyma, supporting the view that these are invasive carcinomas with metastatic potential.

Clinical Behavior

Despite the absence of obvious invasion in the noninvasive variant of MPSC, the data indicate that it behaves as a low-grade serous carcinoma. Stage I noninvasive MPSC has virtually 100% survival. In contrast to noninvasive MPSCs, invasive MPSCs are rarely stage I. The 5-year and 10-year survival rates for patients with advanced-stage noninvasive MPSC are approximately

70% to 85% and 40% to 60%, respectively. After recurrence as invasive carcinoma, the outcome of noninvasive MPSC is similar to that of invasive MPSC, with a progression-free survival of about 2 years and a median survival of 6 years to 7 years (255,256,257).

Invasive MPSC is synonymous with invasive low-grade serous carcinoma. Although the patterns of spread are similar to ordinary high-grade serous carcinoma, low-grade serous carcinoma has a significantly better prognosis (258). Stage III low-grade serous carcinoma is more likely to be stage IIIA as compared to high-grade serous carcinoma, which is nearly always stage IIIC. The natural history of low-grade serous carcinoma is characterized by indolent growth that is resistant to chemotherapy, and recurrences that maintain the well-differentiated histological appearance of the primary tumor, even decades later. Rare exceptions show transformation to high-grade serous carcinoma. The strong association of noninvasive MPSC with invasive implants is a highly significant difference from APSTs. These findings indicate that noninvasive MPSCs are in fact carcinomas, although this view is not shared by all experts.

High-Grade Serous Carcinoma of Ovarian, Tubal, and Peritoneal Origin

High-grade serous carcinoma is the most common type of ovarian cancer and accounts for approximately 50% of ovarian carcinomas. If the clinically and pathologically identical peritoneal and tubal serous carcinomas are included, in addition to carcinosarcoma and undifferentiated carcinoma which are variants, the frequency is over 70% (Table 24.11). In nearly one-third of women with advanced-stage high-grade serous carcinoma, the ovaries are small and display predominantly surface involvement. In the past, these findings have justified a diagnosis of primary peritoneal serous carcinoma.

It has been suggested recently that many or even most serous carcinomas classified as ovarian or peritoneal may actually be tubal carcinomas of fimbrial origin. This is discussed further earlier in this chapter (see Pathogenesis). For practical purposes, the clinical and pathological features of tubal, ovarian and peritoneal high-grade serous carcinomas are identical as described below.

Clinical and Operative Findings

Serous carcinoma most often occurs in the sixth and seventh decades, and the mean age is 63 years for advanced-stage high-grade tumors. Nearly all comprehensively staged patients present in advanced stage with tumor usually disseminated throughout the abdominal and pelvic cavities. Although most advanced-stage cases involve both ovaries microscopically, grossly the ovaries are of normal size in one-third to one-half of cases (includes all cases formerly classified as of peritoneal origin). The vast majority of advanced-stage ovarian carcinomas involve peritoneal surfaces, including the pelvic peritoneum and the surfaces of the bowel and other abdominal organs. Both pelvic and abdominal spread can be by direct extension or metastasis. For example, direct extension to the rectosigmoid, broad ligament, or uterus can occur by contiguous growth, or by exfoliation of malignant cells resulting in seeding of the peritoneal surfaces of the bowel or pelvic peritoneum.

Gross Findings

Serous carcinomas range from microscopic to about 20 cm in greatest dimension. They are typically multilocular, cystic and solid, with soft, friable papillae filling the cyst cavities, and occasionally are completely solid. The cysts contain serous, turbid, or bloody fluid. The external surfaces often display papillae. Solid areas on cut surface are pink to gray. Hemorrhage and necrosis are often present.

When the ovaries are normal in size, the ovarian surfaces often display papillary excrescences of variable size. The appearance of the fallopian tubes is variable. Sometimes they appear normal and may be adherent to the ovarian tumor. Sometimes they cannot be clearly identified. When the fimbriae are identified and carefully examined, they may appear hyperplastic and splayed over the ovarian or tumor surface. In occasional cases, a tumorous papillary outgrowth of the fimbriae constitutes the largest pelvic tumor. Rarely, the fallopian tube is dilated and filled with tumor; in the past, these were the only cases classified as being of tubal origin.

Omental and other peritoneal metastases are characterized by firm nodules with white or gray cut surfaces, which may coalesce to form an omental cake or large masses adherent to bowel and other structures. A grossly normal omentum contains microscopic tumor in 22% of cases.

Microscopic Findings

High-grade serous carcinomas display complex papillary and solid patterns and marked cytologic atypia (Fig. 24.29). Frequently they display a lace-like or labyrinthine pattern characterized by extensive bridging and coalescence of papillae resulting in slit-like spaces. Areas of solid growth, glandular and cribriform patterns are common (Fig. 24.29). Cytoplasmic clear cell change may occur, but characteristic architectural patterns of clear cell carcinoma are not present. Nearly all cases display areas of large, pleomorphic nuclei. Multinucleated tumor giant cells may be present (Fig. 24.29). Bizarre nuclei greater than 50 microns in diameter are characteristic and occur in 86% of advanced-stage tumors (Fig. 24.29). Mitoses, including abnormal mitoses, are numerous and necrosis is often pronounced. There are always at least focal areas with papillary or glandular architecture that permit the diagnosis of a serous carcinoma rather than undifferentiated carcinoma. Psammoma bodies are present in a majority of cases. Rarely, a completely solid carcinoma without any evidence of glands, papillae or other recognizable patterns occurs; this is probably a variant of high-grade serous carcinoma but is designated undifferentiated carcinoma (see below, Undifferentiated Carcinoma).

The fallopian tube mucosa displays intraepithelial carcinoma (STIC) in a substantial proportion of cases (Fig. 24.30). Depending on both interobserver diagnostic reproducibility and on whether the fallopian tubes were entirely embedded for examination, reports of STIC associated with high-grade

FIGURE 24.29. High-grade serous carcinoma displaying solid growth of markedly atypical epithelium with very large hyperchromatic nuclei. Necrosis is present.

FIGURE 24.30. Serous tubal intraepithelial carcinoma displays a stratified layer of markedly atypical tubal epithelium without invasion of the underlying lamina propria of the fallopian tube mucosa.

serous carcinoma vary from 19% to 53% in tumors classified as ovarian and from 29% to 56% in tumors classified as peritoneal (217,259,260,261,262). STIC is usually, but not always, confined to the fimbriae. Complete embedding of the tube increases the yield of STIC. Accordingly, the fallopian tubes should be meticulously examined and entirely embedded for microscopic examination in all high-grade extrauterine serous carcinomas.

Grade

There is a bimodal distribution that separates serous carcinomas into a small group of low-grade carcinomas and a much larger group of high-grade serous carcinomas (263,291,301). These findings along with the distinctly different molecular genetic profile that distinguish low- from high-grade serous carcinoma support the use of a two-tier grading system instead of the traditional three-tier systems of well, moderate and poorly differentiated serous carcinomas. Unlike the two-tier system proposed by Malpica and colleagues from MD Anderson (MDACC), the three-tier system as advocated by Shimizu and associates does not have a histological or molecular basis to separate grades II and III (559). Besides the morphometric and molecular underpinning that support the binary grading system, this division reveals distinctive epidemiologic differences (264), more consistently separates prognostic groups, and has been validated to be reproducible among generalists and specialists (265). Low-grade serous carcinoma is characterized by uniform cells with mild to moderate nuclear atypia, whereas high-grade tumors have pleomorphic cells with marked nuclear atypia. Low-grade tumors have a mitotic index less than 12 per 10 HPF, and usually much lower, while high-grade tumors usually display greater than 12 per 10 HPF.

Mucinous Tumors

Primary ovarian mucinous tumors include cystadenomas, APMT, and carcinomas (intraepithelial and invasive). Cystadenomas and APMT are noninvasive and are distinguished from each another primarily by their degree of complexity and epithelial proliferation. The invasive carcinomas are distinguished by the presence of stromal invasion. There is a morphologic spectrum of epithelial proliferation in mucinous tumors that includes cystadenomas with focal epithelial proliferation, and APMT with intraepithelial carcinoma and/or microinvasion,

providing evidence that these tumors comprise a biologic spectrum with individual types representing steps in the sequence of ovarian mucinous carcinogenesis.

The other types of mucinous tumors seen in the ovary include metastatic mucinous carcinomas, most commonly from the gastrointestinal tract, and low-grade mucinous tumors of appendiceal origin, secondarily involving the ovary in association with the clinical syndrome of pseudomyxoma peritonei. Both metastatic mucinous carcinomas and low-grade mucinous tumors of appendiceal origin can simulate primary ovarian mucinous tumors, usually APMT and primary ovarian mucinous carcinoma (210). It is now clear that primary ovarian mucinous carcinomas are much less common than previously believed. Furthermore, most mucinous carcinomas within the ovary prove to be metastatic (197).

Benign Mucinous Tumors, Intestinal and Mullerian (Seromucinous, Endocervical-Like) Types

Mucinous cystadenomas (including the mullerian type; see below) comprise 15% of benign ovarian epithelial neoplasms (Table 24.10). About 80% are of the intestinal type. The mean patient age is about 50 years. Intestinal-type mucinous cystadenomas are unilocular or multilocular tumors of variable size, ranging from a few centimeters to over 30 cm, with a mean of about 10 cm. They are typically unilateral (95%). The capsule is typically thick and white with a smooth outer surface. The cysts contain thick gelatinous material. They are composed of glands and cysts lined by simple nonstratified mucinous epithelium (Fig. 24.31). When epithelial atypia or proliferation resembling APMT is present, this feature must be limited. Tumors composed predominantly of cystadenoma with less than 10% of APMT are diagnosed as mucinous cystadenoma with focal proliferation or focal atypia (210). Up to 18% of mucinous cystadenomas contain transitional cell nests, also referred to as a Brenner tumor component, often in a discrete nodule, which is usually interpreted as a concurrent Brenner tumor (Fig. 24.32) (285). Occasionally, cystadenomas have endocervical-type mucinous epithelium. These are referred to as mullerian type mucinous, endocervical-like mucinous, or seromucinous cystadenoma. They usually have a papillary architecture in contrast to the pure glandular pattern of the intestinal-type.

FIGURE 24.31. Mucinous cystadenoma shows a single layer of columnar epithelium with small basal nuclei and abundant mucin-rich cytoplasm.

FIGURE 24.32. Mixed mucinous-Brenner tumor with several Brenner-type (transitional) nests within the stroma toward the top left, and a single layer of mucinous epithelium at bottom right.

Atypical Proliferative Mucinous Tumor (Mucinous Borderline Tumor, Intestinal Type)

Although the borderline category was intended mainly for serous tumors, the concept was also extended to mucinous tumors since they also appeared to have intermediate forms. These were most often characterized by pseudomyxoma peritonei and were felt to be analogous to serous borderline tumors with peritoneal implants. There are 2 types of APMT/MBT corresponding to the 2 types of mucinous cystadenoma: the gastrointestinal type, and the endocervical-like (mullerian, or seromucinous) type. The gastrointestinal type of APMT is typically a large, multicystic tumor with a smooth capsule, and is usually unilateral (>95%) with median size of about 20 cm to 22 cm (210,266). The locules of the tumor are usually filled with mucinous material and the lining appears smooth, without grossly evident papillations. Microscopically, the cysts are lined by stratified, proliferative gastrointestinal-type mucinous epithelium exhibiting tufted and villoglandular or papillary intraglandular growth and displaying mild to moderate nuclear atypia; stromal invasion is absent (Fig. 24.33).

Review of the literature on tumors meeting the diagnostic criteria for APMT, gastrointestinal type, reveals a benign behavior. Over 600 stage I tumors have been reported and fewer than

FIGURE 24.33. Atypical proliferative mucinous tumor shows glandular proliferation, cellular stratification, and mild cytologic atypia.

1% of patients have died of disease. Most fatal tumors had an unknown degree of sampling and are reported in the older literature; most recent studies report 100% survival (210). Approximately 100 “advanced-stage MBTs” have been reported, with nearly 50% mortality. Of these, about 85% have been associated with pseudomyxoma peritonei. More recent studies have established that virtually all cases of pseudomyxoma peritonei are of gastrointestinal (usually appendiceal), not ovarian, origin (see pseudomyxoma peritonei, below) (210). The remaining 15% of advanced-stage APMTs reported are probably metastatic mucinous carcinomas that masquerade as MBTs. Therefore, there is no clear pathologic description of peritoneal implants associated with true primary ovarian APMT, and therefore, for practical purpose, advanced-stage APMT does not even exist. When these latter tumors are removed from the APMT category, the remainder consist of stage I tumors with benign behavior.

Atypical Proliferative Mucinous Tumors, Seromucinous (Endocervical-Like or Mullerian) Type

The seromucinous type of APMT (atypical proliferative seromucinous tumor, APSMT) is grossly, microscopically and immunophenotypically distinct from the gastrointestinal-type tumor. The seromucinous tumors are much less common, smaller, more frequently bilateral, architecturally resemble APST, and are much more often associated with endometriosis (over one-third of cases). In addition, they frequently display acute inflammation of the stroma, and a combination of endocervical mucinous and serous (ciliated) type epithelium, often admixed with minor components (<10%) of other cell types. Based on a small number of studies, these tumors appear to exhibit benign behavior (210).

Atypical Proliferative Mucinous Tumors with Intraepithelial Carcinoma

Noninvasive mucinous tumors with marked nuclear atypia are classified as APMT with intraepithelial carcinoma. Intraepithelial carcinomas confined to the ovaries have an excellent prognosis (about 95% survival, with most recent studies reporting 100% survival). A small number of so-called “advanced-stage intraepithelial mucinous carcinomas” have been reported, with a few tumor deaths. In view of the ability of metastatic mucinous carcinomas to simulate APMT with intraepithelial carcinoma, it is likely that some of these apparent advanced-stage intraepithelial carcinomas with adverse outcomes represent metastases from occult extraovarian primary tumors. It is also possible that some of these represent true primary ovarian mucinous carcinomas with foci of destructive invasion in unsampled tissue.

Atypical Proliferative Mucinous Tumors with Microinvasion

Microinvasion in APMT has been defined as either small foci of stromal invasion characterized by single cells, glands or small clusters or nests of mucinous epithelial cells within the stroma, or as small foci of confluent glandular or cribriform growth within the stroma. The size criterion for each focus has varied from 2 mm to 5 mm, with no requirement regarding the number of foci allowed. Some tumors with microinvasion also have intraepithelial carcinoma. Based on the relatively small number of microinvasive tumors with follow-up that have been reported, no well-documented recurrences or deaths due to disease have been reported.

Mucinous Tumors Associated with Pseudomyxoma Peritonei

Pseudomyxoma peritonei has historically referred to the presence of mucinous ascites or mucoid nodules adherent to peritoneal surfaces and has not had a consistently applied histopathologic definition. Recent studies have clarified that pseudomyxoma peritonei is a clinicopathologic syndrome in which mucoid peritoneal nodules and/or mucinous ascites are accompanied by low-grade neoplastic mucinous epithelium associated with pools of extracellular mucin. Morphologic, immunohistochemical, and molecular genetic studies have provided compelling evidence that virtually all cases of pseudomyxoma peritonei are derived from low-grade mucinous adenomas, usually of the appendix, and that the ovarian involvement is secondary (210). When intraoperative consultation with frozen section leads to a diagnosis of a mucinous ovarian tumor in the setting of pseudomyxoma peritonei, appendectomy and thorough examination of the gastrointestinal and pancreaticobiliary tracts should be performed. The pathologist should examine the entire appendix microscopically. The rare exception to the gastrointestinal origin of pseudomyxoma peritonei is the occurrence of mucinous tumors arising in ovarian mature cystic teratomas associated with mucinous ascites (267). The terms “disseminated peritoneal adenomucinosis” (DPAM) and “involvement by low-grade appendiceal mucinous neoplasm” are now preferred as specific pathologic diagnostic terms for these low-grade peritoneal and ovarian mucinous tumors, respectively.

Invasive Mucinous Carcinomas

Clinical and Operative Findings

Mucinous carcinomas of the intestinal type are rare and comprise 3% of ovarian carcinomas (Table 24.11). Primary ovarian mucinous carcinomas, like APMT, most often present as large unilateral ovarian masses without evidence of ovarian surface involvement or extraovarian disease. The vast majority present in FIGO stage I.

Gross Findings

The gross findings are similar to APMT in that the tumors are typically large, unilateral, multicystic mucus-containing tumors with smooth white capsules and have mean and median sizes of 18 cm to 22 cm. They may contain solid areas and foci of necrosis and hemorrhage.

Microscopic Findings

Mucinous carcinomas of intestinal type typically are architecturally well-differentiated and display a variety of glandular patterns, with most tumors containing areas of APMT adjacent to areas of carcinoma. In addition to destructive stromal invasion, there is a second pattern of invasion termed the “confluent glandular” or “expansile” pattern. In this pattern, the glandular epithelium is markedly crowded and interconnected with little intervening stroma (268) (Fig. 24.34). Primary ovarian mucinous carcinomas commonly exhibit this pattern of invasion, and the presence of an infiltrative pattern of stromal invasion should raise concern for metastatic mucinous carcinoma. For tumors composed predominantly of APMT, the foci of confluent growth should measure more than the upper size limit allowed for microinvasion (5 mm) to qualify for the diagnosis of invasive carcinoma. Mucinous carcinomas of the seromucinous (mullerian or endocervical-like) type are quite uncommon. They are clinically and grossly similar to the atypical proliferative tumors of this type. Microscopically, they also resemble APMT but exhibit destructive stromal invasion or sufficient complex or confluent growth to be classified as carcinoma. Like their

FIGURE 24.34. Mucinous carcinoma with confluent glandular pattern of invasion manifested by complex and interconnected epithelial proliferation lacking stroma.

noninvasive counterparts, they have a strong association with endometriosis.

As discussed above, it is critical when evaluating a mucinous carcinoma involving the ovary to consider the possibility of an extraovarian primary. Metastatic mucinous carcinomas are usually readily recognized as such when the ovarian tumors exhibit at least 2 of the following features: bilaterality, smaller size (typically less than 10 cm to 12 cm), ovarian surface involvement, a nodular pattern of ovarian involvement and a haphazard infiltrative pattern of stromal invasion. Immunohistochemistry can be of great value in this distinction. In general, primary ovarian mucinous tumors are positive for CK7 and variably positive for CK20. Most gastrointestinal carcinomas are negative for CK7 and positive for CK20. HPV and p16 staining can help assess for a cervical primary. Mammaglobin and GCDFP-15 are positive in most breast carcinomas and negative in ovarian mucinous tumors. DPC4 is positive in ovarian mucinous carcinoma and often negative in pancreatic carcinoma. ER and PR are generally not helpful markers as they are usually negative in primary ovarian mucinous tumors. An algorithm has been proposed to assist in the distinction of primary versus metastatic mucinous carcinoma, particularly at the time of intraoperative evaluation when only limited histologic material can be examined. As originally proposed, bilateral mucinous carcinomas and unilateral ones smaller than 10 cm are metastatic, and unilateral ones larger than 10 cm are primary (197). This algorithm correctly classified 90% of mucinous carcinomas. Subsequent studies have confirmed and refined the algorithm, also with close to 90% accuracy, and suggest that 13 cm is a better cutoff than 10 cm (226). Because these size measurements are often not extremely precise and may be taken after the tumor has been partially deflated and emptied of its mucinous contents, the 10 cm to 15 cm size range is of lesser predictive value (269).

Clinical Behavior

Patients with stage I mucinous carcinomas have a survival of about 90%, similar to comprehensively staged FIGO stage I patients with the other cell types of ovarian carcinoma. For patients with APMT with microinvasion and/or intraepithelial carcinoma, a staging procedure is unlikely to yield positive findings, but no data are available to address its value. Bona fide advanced-stage mucinous carcinomas have a poor prognosis, and limited data based on a recent GOG study suggests that the survival is significantly worse than that for serous carcinomas (270).

Metastatic Mucinous Carcinomas

It is now clear that the historical canon that mucinous carcinoma is a common type of primary ovarian cancer is incorrect. As noted earlier, 80% of mucinous carcinomas that involve the ovaries are metastatic from other sites. Metastatic mucinous carcinomas are typically bilateral, small (typically less than 10 to 12 cm), display ovarian surface and superficial cortical involvement, a nodular pattern of ovarian involvement, and a haphazard infiltrative pattern of stromal invasion. However, some metastatic mucinous carcinomas can exhibit gross and microscopic features simulating a primary ovarian mucinous tumor. In particular, metastases can be large, unilateral (thus misclassified by the algorithm discussed earlier), and multicystic and can display deceptive patterns of ovarian involvement. Recognizing metastases is especially problematic when the ovarian tumor is the initial manifestation of disease and an extraovarian primary mucinous carcinoma is occult. When mucinous carcinomas in the ovaries are rigorously classified based on refined criteria and awareness of the deceptive patterns, metastatic mucinous carcinomas are much more commonly encountered than primary ovarian mucinous carcinomas (197). In general, the presence of a mucinous carcinoma in the ovary, particularly if extraovarian disease is present, should always prompt the surgeon and pathologist to consider the possibility of metastatic mucinous carcinoma. Immunohistochemical analysis can be useful for identifying some metastatic mucinous carcinoma, but clinical evaluation is essential to exclude a clinically occult extraovarian source.

Endometrioid Tumors

The vast majority of endometrioid ovarian neoplasms are carcinomas. Endometrioid adenofibromas and atypical proliferative endometrioid tumors (APET) are quite uncommon. However, endometriosis is quite common and now regarded as neoplastic. Consequently, endometriomas and endometriotic cysts are the true benign endometrioid ovarian neoplasms, notwithstanding the likelihood that their ultimate origin is from the endometrium via tubal reflux. Molecular biological studies have shown that endometrioid ovarian carcinomas have similarities with and differences from their uterine counterparts.

Endometrioid Adenofibromas

Endometrioid adenofibromas are uncommon benign tumors that comprise less than 1% of ovarian epithelial neoplasms, and are unilateral 83% of the time. The median age at diagnosis is 57 years. The mean diameter is about 10 cm. The external surface is smooth and the cut surface is densely fibrous, often with intermixed cystic areas creating a honeycomb appearance. Microscopically, the dominant pattern is that of an adenofibroma or cystadenofibroma. The epithelial elements are arranged in branching tubular glands and cysts, and usually resemble those of proliferative or mildly hyperplastic endometrium. Endometrioid adenofibromas are frequently associated with endometriosis.

Atypical Proliferative Endometrioid Tumors

There is a spectrum of epithelial proliferation, glandular crowding, and cytologic atypia in benign endometrioid neoplasms ranging from mild atypia, mild glandular crowding, and epithelial stratification slightly beyond that seen in endometrioid adenofibromas, to confluent epithelial proliferation lacking stromal support in areas up to 5 mm in diameter resembling atypical hyperplasia and well-differentiated adenocarcinoma of the endometrium. A variety of terms have been employed for

these tumors, including proliferating or proliferative endometrioid tumor, atypical endometrioid adenofibroma, endometrioid tumor of low malignant potential, endometrioid borderline tumor and APET. APET with microinvasion (<5 mm), which is very rare, constitutes the upper end of this spectrum after which a diagnosis of low-grade endometrioid carcinoma is used. The behavior of all of the tumors up to and including those with microinvasion, has been benign.

Clinical and Operative Findings

APET comprise only 0.2% of ovarian epithelial neoplasms. Among 5 series, there were 134 patients with a mean age of about 51 years. Six patients (4%) had bilateral tumors, and all but 2 were confined to the ovaries. The mean tumor size was about 9 cm. The characteristic gross appearance is cystic in two-thirds and solid and cystic in the rest; the cyst fluid is usually hemorrhagic, brown or green. Many patients have had endometriosis and some have also had endometrial hyperplasia.

The 2 characteristic microscopic architectural appearances of APET are adenofibromatous and glandular/papillary. The glandular/papillary proliferation can show varying degrees of glandular complexity and crowding. When the glandular proliferation becomes confluent, this is considered evidence of invasion and is classified as microinvasion if the confluent area is less than 5 mm. Some investigators prefer to classify these as APET with intraepithelial carcinoma. A confluent epithelial proliferation or invasion that exceeds 5 mm in diameter warrants a diagnosis of carcinoma (268). The glands show crowding, mild or moderate cytologic atypia, epithelial stratification, and often display tufting and bridging. Severe cytologic atypia warrants a diagnosis of intraepithelial carcinoma, but this is quite rare. Among 134 reported APETs, all of those with clinical follow-up have had a benign behavior after a mean follow-up period of approximately 5 years (205,271). Rarely, an endometriotic cyst is lined by markedly atypical epithelial cells that have cytologic features of malignancy. If the lesion is well-sampled and invasion is not found, a designation of APET with intraepithelial carcinoma should be used.

Endometrioid Adenocarcinoma

In the older literature, about 15% to 20% of reported ovarian carcinomas are endometrioid, up to 25% in some reports (272), but when strict criteria are applied, the figure is lower and probably in the range of 10% to 15%. When very strict criteria are used, requiring a readily recognized resemblance to uterine endometrioid carcinoma and classifying nonspecific high-grade adenocarcinomas as serous carcinoma as is currently preferred (273,274), the figure is about 7.2% (Table 24.11).

Clinical and Operative Findings

These tumors are most common in the fifth and sixth decades, and the mean patient age at diagnosis is 55 years to 58 years. Tumor size ranges from 12 cm to 20 cm with a mean of about 15 cm. The stage distribution differs significantly from serous carcinoma. A high proportion of endometrioid carcinomas are diagnosed in stage I: 43% in a review of 874 cases from 19 series, and 53% at the Washington Hospital Center (Table 24.11). About 13% of early-stage (FIGO I–II) cases are bilateral. Endometriosis, which may be extraovarian, in the ipsilateral or contralateral ovary or within the tumor itself, is found in at least 15% to 20% of patients.

Gross Findings

Endometrioid carcinomas have a smooth outer surface. On cut section, they are solid and cystic, with the cysts containing friable soft masses and bloody fluid. Cysts occasionally contain

mucus or greenish fluid. Less commonly, the tumor is solid with extensive hemorrhage and necrosis. Tumors arising in endometriosis may display gross findings of an endometriotic cyst containing chocolate-colored fluid, with one or more solid nodules or papillary excrescences protruding from the wall and containing carcinoma.

Microscopic Findings

Destructive infiltrative growth characterizes one pattern of endometrioid carcinoma. This pattern is characterized by angulated glands with an infiltrative pattern, jagged irregularly spaced and unevenly shaped nests and solid sheets with jagged edges. More commonly, a confluent glandular epithelial proliferation exceeding 5 mm (the limit for microinvasion) is present. This pattern is characterized by extensive glandular branching, budding, true cribriform architecture and highly complex papillary proliferations (Fig. 24.35). Confluent or expansile invasion is the predominant pattern in most endometrioid carcinomas (268).

Architecturally well-differentiated endometrioid adenocarcinoma accounts for the majority of cases and is characterized by a confluent or cribriform proliferation of glands lined by tall, stratified columnar epithelium with sharp luminal margins (Fig. 24.36). A villoglandular growth pattern also occurs. Despite the low-grade architecture, high-grade nuclear features can be observed, at least focally. Mitotic figures are common. Squamous differentiation is present in up to 50% of cases. Focal secretory changes are seen in up to a third of cases. In the majority of cases, a component of endometriosis, endometrioid adenofibroma or APET can be identified.

Moderately and poorly differentiated endometrioid carcinomas show solid growth, complex glandular and microglandular patterns with marked nuclear pleomorphism and mitotic activity, however the majority of high-grade carcinomas with these features are usually classified as serous. It has been suggested that solid areas in some endometrioid adenocarcinomas may reflect an undifferentiated component (275).

At present, clinicopathologic and molecular data indicate that it is important to be strict about classifying an adenocarcinoma as endometrioid type. Most predominantly glandular non-clear cell, nonmucinous high-grade ovarian carcinomas should be classified as serous carcinoma. Glandular, cribriform, and solid patterns are common in serous carcinoma (273,274). A bonafide endometrioid adenocarcinoma should resemble eutopic endometrial carcinomas. Foci of squamous differentiation, secretory change, endometriosis, or endometrioid

FIGURE 24.35. Endometrioid adenocarcinoma displaying an infiltrative pattern of cellular islands containing endometrioid-type epithelium with a cribriform pattern.

FIGURE 24.36. Endometrioid adenocarcinoma, high magnification (same case as Fig. 24.35) showing tall columnar epithelium with sharply punched out glandular spaces and mild to moderate cytologic atypia.

adenofibroma can be of value in supporting the diagnosis of endometrioid carcinoma.

Peritoneal keratin granulomas may be found in women with endometrioid ovarian carcinomas, presumably as a result of rupture of the neoplasm or exfoliation of squamous cells. Follow-up of a limited number of these patients reveals that these lesions have no prognostic significance and therefore should not be considered evidence of advanced-stage disease.

Clinical Behavior

Overall, endometrioid carcinomas of the ovary have a better prognosis than typical serous carcinomas due to the high proportion of stage I cases. The favorable prognosis may also result, in part, from the young age of most women diagnosed with endometrioid carcinoma and the high frequency of low-grade tumors. However, data on the influence of grade on prognosis are less clear because grade and stage are mutually confounding factors (see below, Prognostic factors). One recent large prospective series found that in stages II and III, the prognosis was significantly better for endometrioid as compared to serous carcinoma. In that series, however, endometrioid carcinomas were significantly more likely to be optimally debulked as compared to serous carcinomas, and occurred in younger women. In addition, neither substage nor grade was considered (272).

Endometrioid Carcinoma Associated with Uterine Endometrial Carcinoma

Approximately 14% of women with endometrioid ovarian carcinoma also have endometrial cancer of the uterine corpus. Endometrial hyperplasia is also commonly present. As both tumors are usually well-differentiated endometrioid adenocarcinomas, they resemble each other, and excluding the possibility that the ovarian tumor is metastatic can be a problem. Usually this can be determined based on a careful evaluation of the clinicopathologic features (276). If the uterine endometrial tumor is low-grade with no or only inner half myometrial invasion, its metastatic potential is very low and the ovarian tumor can confidently be regarded as independent. If the endometrial tumor is high-grade and/or deeply myoinvasive, the features of the ovarian tumors come into play. Bilaterality and a multinodular pattern, as well as other patterns characteristic of metastatic disease indicate metastatic tumor. Close association of the ovarian tumors with either an underlying adenofibroma or endometriosis, if present, can provide evidence that the ovarian tumor is independent.

The median age of women who present with simultaneous uterine and endometrioid ovarian cancer is about 50 years, significantly lower than that the median age of presentation for high-grade serous carcinomas (about 63 yr), and close to that for all women with endometrioid carcinomas (55 to 58 yr). The median ovarian tumor size is about 9 cm. The majority of tumors in both sites are well differentiated. The 5-year survival is 70% to 92%, and the median survival is 10 years or longer (277).

Over the last few years, investigators have employed several different molecular strategies to assess the likelihood that simultaneously detected endometrioid adenocarcinomas in the ovary and endometrium represent a single versus 2 independent primaries. Most of these have relied upon the presence or absence of shared genetic alterations in the ovarian and endometrial adenocarcinomas. The difficulty of correctly classifying some of these cases is highlighted by the fact that virtually every published series of synchronous ovarian and uterine endometrioid adenocarcinomas includes cases that, after being diagnosed using standard histologic criteria, would be reclassified based on molecular analysis (278).

Endometrioid Carcinoma Arising in Endometriosis

On average, 15% to 20% of endometrioid carcinomas of the ovary are associated with endometriosis which may occur within the tumor, the ipsilateral or contralateral ovary, or elsewhere. The frequency can be as high as 42%. It is likely that when strict criteria are applied to diagnose endometrioid carcinoma (see above), some cases would be reclassified as high-grade serous carcinomas and therefore the percentage of endometrioid carcinomas associated with endometriosis would be higher. The majority of bona fide endometrioid carcinomas can be shown to be associated with endometriosis when extensive histologic sampling and meticulous searching for the histologic features of endometriosis are performed, and strict diagnostic criteria are used. In only a minority of cases, however, can direct continuity from endometriosis to atypical hyperplasia to carcinoma be demonstrated. This is most commonly seen in the lining of an endometriotic cyst, which may display a thickening of the cyst wall, papillary excrescences, or a nodule protruding into the cyst. The mean age of women with endometrioid carcinoma associated with endometriosis is 5 to 10 years younger than for women whose endometrioid tumors are unassociated with endometriosis. Tumors associated with endometriosis, and particularly those arising in an endometriotic cyst, are usually architecturally well-differentiated and stage I, and therefore the prognosis is excellent. On rare occasions, a limited atypical epithelial proliferation in an endometriotic cyst will raise the differential diagnosis of atypical hyperplasia similar to the type seen in the uterine corpus, versus well-differentiated endometrioid adenocarcinoma. In such cases, criteria for this distinction used in the uterine corpus have been applied with minor modifications.

The identification of genetic alterations in endometriotic lesions and the observation of a morphological transition from endometriosis to carcinoma in over one-third of cases indicates that endometriosis is a precursor of endometrioid carcinoma. Progression from endometriosis to benign endometrioid neoplasm to well-differentiated endometrioid carcinoma is analogous to that proposed for progression of low-grade serous carcinoma from serous borderline tumor. Hence, low-grade (well-differentiated) endometrioid carcinomas are classified as Type I tumors in the dualistic model of ovarian cancer pathogenesis (see Pathogenesis, earlier in this chapter). Classification of high-grade endometrioid carcinomas is less clear. Overlap of both morphological and molecular features between high-grade endometrioid and high-grade serous carcinomas has led most authorities to classify the vast majority of gland forming

or near-solid cytologically high-grade ovarian carcinomas to the serous category, to the degree that “true” high-grade endometrioid carcinomas are considered to be very uncommon (273,274).

Clear cell Tumors

The vast majority of clear cell neoplasms of the ovaries are carcinomas and they comprise 8.5% of ovarian carcinomas (Table 24.11). Clear cell adenofibromas and atypical proliferative clear cell neoplasms are vanishingly rare (Table 24.10).

Clear cell Adenofibromas

These are among the rarest of the ovarian epithelial tumors; no cases were found among 1,247 consecutive epithelial tumors (Table 24.10). Among 12 reported cases of benign clear cell tumors, the mean age was 45 years. One tumor was bilateral. The median diameter was 12 cm. The tumors display a smooth lobulated external surface and the cut surfaces have a fine honeycomb appearance with minute cysts embedded in firm rubbery stroma. The cyst fluid is clear. Microscopically, the tumor is characterized by tubular glands lined by one or 2 layers of peg-like or hobnail cells that may bulge into the lumen or are flattened. The cytoplasm is either scanty, often in the hobnail cells, or abundant clear, granular or eosinophilic in the large polyhedral cells. Nuclear atypia and mitotic activity are minimal. The clinical behavior appears benign, although data are very limited.

Atypical Proliferative Clear Cell Tumors

Atypical proliferative clear cell tumors (APCCT) comprise 0.2% of ovarian epithelial tumors (Table 24.10). Among approximately 30 cases of APCCT (clear cell adenofibroma of borderline malignancy) in the literature, the mean age is 60 to 70 years. The mean tumor diameter is about 15 cm. The gross appearance is similar to that of the clear cell adenofibroma, but in addition there are softer and fleshier areas. Microscopically, the architecture is similar to the clear cell adenofibroma, but glands are more crowded. The tumor has greater epithelial proliferation and atypia than the adenofibroma and lacks stromal invasion. The cell types lining the glands and cystic spaces are similar to those in benign tumors but display significant nuclear atypia with coarse chromatin clumping, prominent nucleoli, and mitotic activity up to 3 per 10 hpf. The epithelium may display stratification and budding; true papillary structures are uncommon. Small solid nests of clear cells, significant gland crowding or papillary growth should raise the suspicion of stromal invasion. Distinction of an APCCT from clear cell carcinoma is one of the most difficult distinctions in gynecologic pathology. Some clear cell carcinomas lack an obviously infiltrative pattern and are characterized solely by crowded glands. The point at which gland crowding in a clear cell neoplasm reflects invasion is not well defined. The vast majority of tumors in which this differential is considered are best classified as clear cell carcinoma.

Occasionally, an endometriotic cyst is lined by atypical epithelial cells with clear cytoplasm. This has been designated “atypical endometriosis”. Rarely, cytologic features of malignancy are present in this setting. If the lesion is well-sampled and invasion is not found, the lesion is classified as APCCT with intraepithelial carcinoma. Microinvasion should be diagnosed if invasive areas measure less than 5 mm, but this finding should prompt additional sampling to look for diagnostic features of carcinoma. There are virtually no published data on clear cell tumors with microinvasion or intraepithelial carcinoma, both of which are exceedingly rare. Peritoneal “implants” have not been described associated with these tumors. Among the limited reported APCCTs, there is one alleged recurrence and no tumor deaths.

Clear cell Carcinomas

The accurate and reproducible diagnosis of ovarian clear cell carcinoma now relies heavily on recent data indicating that serous carcinomas can have areas of clear cells, and that such tumors have the other pathologic and immunohistochemical features of serous carcinoma and should be diagnosed as such (279). Old literature on clear cell carcinomas may therefore be inaccurate due to this recently emphasized classification problem.

Clinical and Operative Findings

The mean age of patients with clear cell carcinoma is 50 to 53 years. Symptoms usually relate to a pelvic or abdominal mass. Clear cell carcinoma is the most common epithelial ovarian neoplasm to be associated with vascular thrombotic events (18% to 46% of patients) and paraneoplastic hypercalcemia (2% to 10%).

The relationship with endometriosis is strongest for clear cell carcinoma among all cell types of ovarian carcinoma. Accordingly, endometriotic implants are commonly present in close proximity to the tumor or elsewhere in the pelvis or abdomen. About 45% to 60% of clear cell carcinomas present in FIGO stage I, and 10% to 20% in stage II (280) (Table 24.11). Eight percent are bilateral; 4% of stage I cases are bilateral (281). Several recent studies have shown that stage I clear cell carcinoma is more likely to be stage IC (50% to 74%) as compared to the other cell types (282,283,284). The reason for this is not clear, but it seems to be correlated with a higher risk of tumor rupture; this may be due to the extent and inherent difficulty in dissecting adhesions due to endometriosis.

Gross Findings

Tumors range up to 30 cm with a mean diameter of about 13 cm to 15 cm. Although they may be solid and fibrous with a honeycomb cut surface resembling benign and atypical proliferative clear cell tumors, more commonly the cut surfaces reveal a thick-walled unilocular cyst with multiple yellow-beige fleshy nodules protruding into the lumen, or a multiloculated cystic mass with cysts containing watery or mucinous fluid. Most tumors arise in endometriosis and often display features of an endometriotic cyst that typically contains chocolate-brown fluid, and a thickened, polypoid, or nodular area in the wall, or a larger solid area reflecting the focus of malignant transformation.

Microscopic Findings

Clear cell carcinomas display several different patterns, which often occur together (Figs. 24.37, 24.38, and 24.39). These include papillary, tubulocystic and solid. In a minority of cases, there is a prominent adenofibromatous component. Recently, some investigators have subdivided clear cell carcinomas into those arising in a cyst and those that are more solid and adenofibromatous. The cystic tumors are more frequently papillary, whereas the tubulocystic pattern (Fig. 24.37) tends to dominate in the adenofibromatous tumors. The cystic variant is more frequently associated with endometriosis, suggesting that the 2 variants arise along different pathways (280).

The solid pattern of clear cell carcinoma is characterized by sheets of polyhedral cells with abundant, clear cytoplasm separated by delicate fibrovascular septae or dense fibrotic stroma (Fig. 24.38). The papillary pattern is characterized by papillae that are either fibrotic but more often are hyalinized. In fact, the hyalinized papillary cores are a very characteristic feature of this tumor. The tubulocystic pattern is characterized by varying size tubules and cysts (Fig. 24.37). The majority of tumors display combinations of all of these patterns. Despite its name, many of the cells comprising clear cell carcinoma contain slightly granular eosinophilic cytoplasm. The cells with clear cytoplasm

FIGURE 24.37. Clear cell carcinoma, tubulocystic pattern. This pattern is deceptively benign-appearing, characterized by cystic and glandular spaces lined by flattened to low cuboidal epithelium, often with only minimal cytologic atypia.

FIGURE 24.38. Clear cell carcinoma, glandular and solid pattern with an infiltrative pattern of small glands with severe cytologic atypia.

FIGURE 24.39. Clear cell carcinoma, hobnail pattern, displaying epithelial stratification of markedly atypical cells with clear cytoplasm and snouts protruding into the gland lumen.

contain glycogen. The nuclei vary from small and rounded and angular to large and pleomorphic with prominent nucleoli (Fig. 24.39). Often, the nuclear grade within a tumor varies from mild to markedly atypical. However, at least focally the nuclear grade is nearly always high. Clear cell carcinoma, though officially not graded, is considered high-grade in all cases. Mitotic activity tends to be low, exceeding 10 per 10 HPF in only one-fourth of cases. In the tubulocystic and papillary patterns, the cells often have a hobnail appearance with the nucleus protruding from the papillae, tubule or cyst, into the lumen (Fig. 24.39). Occasionally, the epithelium lining the tubules and cysts is flattened and the nuclear grade is low in these areas, but careful scrutiny will reveal cells with high-grade nuclei elsewhere.

Clear cell carcinomas arising in endometriosis are usually cystic and may display atypia of the lining of an endometriotic cyst with either a gradual or abrupt transition to cytologic features of malignancy and invasive clear cell carcinoma. This can be seen in one-third of clear cell carcinomas. If cytologic atypia is marked and invasion is absent, a diagnosis of APCCT with intraepithelial carcinoma is warranted. Cystic clear cell carcinomas are significantly more likely to be associated with endometriosis and atypical endometriosis as compared to the adenofibromatous type (280).

About one-third of reported ovarian clear cell carcinomas are associated with endometriosis either in the involved ovary or elsewhere in the pelvis or abdomen. These figures vary widely and many recent studies have observed 50% or greater associated with endometriosis (205). One recent large study found endometriosis to be present in about 90% of cystic clear cell carcinomas, while the association of endometriosis with adenofibromatous clear cell carcinomas was only 44% (280). When carefully sought, nearly all ovarian clear cell carcinomas are associated with endometriosis and at least one-third of cases can be demonstrated to have arisen within endometriosis, usually an endometriotic cyst.

Clinical Behavior

There are conflicting data on the behavior of clear cell carcinoma. In some studies, the prognosis appears similar to that for other ovarian carcinomas, but in others, the prognosis is said to be worse. Comprehensively staged ovarian carcinoma (of all histologic types) in FIGO stage I has a 90% or better 5-year survival, and several recent studies have shown comparable survival rates for clear cell carcinoma. Evidence that clear cell histology is an adverse prognostic factor in advanced stage is somewhat more convincing. However, recent refinements in the criteria for cell type assignment suggest that clear cell carcinoma has been overdiagnosed, as a small but significant minority of high-grade serous carcinomas contain clear cells. This misclassification removes some high-grade serous carcinomas from the serous group and thereby improves the survival of serous carcinomas by increasing the proportion of low-grade serous carcinoma (258). The improved survival of serous carcinoma may then appear better than that for clear cell carcinoma, which is always a high-grade tumor.

Brenner (Transitional Cell) Tumors

Transitional cell tumors comprise 10% of ovarian epithelial tumors. Nearly all of these are benign Brenner tumors; atypical proliferative and malignant forms are very uncommon. The transitional epithelial cell type, characterized by a relatively uniform population of stratified cells with ovoid nuclei displaying nuclear grooves, is named because of its resemblance to urothelium. Evidence suggests that Brenner tumors have some true urothelial differentiation, while transitional cell carcinoma

(unassociated with a benign Brenner component) is a variant of high-grade serous carcinoma.

Brenner (Benign Transitional Cell) Tumors

The mean patient age at diagnosis is 56 years. These are common incidental findings and are often microscopic in size. Most tumors are 2 cm or smaller. Multiple microscopic tumors are seen in 17% of patients. Occasionally they are large and may exceed 10 cm. Most tumors are well-circumscribed, firm and rubbery, with a smooth or slightly bosselated serosal surface. The cut surfaces are typically solid and fibrous, usually gray, white or yellow, and may be whorled or lobulated; occasionally a cystic component is present.

Microscopically, the characteristic feature is sharply demarcated epithelial nests in a dense fibrous stroma (Fig. 24.40). The epithelial cells are uniform in size with prominent cell borders and pale to eosinophilic cytoplasm. The nuclei are oval and longitudinal grooves are usually present. Atypia and mitotic activity are generally not present. A metaplastic mucinous component may occasionally form the dominant part of the tumor and accounts for the association of Brenner tumors with mucinous cystadenomas. It has been suggested that the majority of nonteratomatous mucinous tumors arise in Brenner tumors as an overgrowth of the mucinous component (285) (see below, Mixed Brenner-mucinous tumors). The stroma varies from closely resembling ovarian cortical stroma to densely fibrous. Hyalinized areas are common, and dystrophic, spiculated calcification is present in about half of the cases. The clinical behavior is benign.

Mixed Brenner-Mucinous Tumors

Tumors containing both Brenner and mucinous components are more common than previously appreciated (Fig. 24.32). These are believed to be variants of Brenner tumor and can be classified as metaplastic Brenner tumor or mixed Brenner-mucinous tumor. One-fourth of benign ovarian epithelial tumors that have a mucinous component also contain a Brenner component. Conversely, 16% of tumors with a Brenner component contain a mucinous component. These patients are significantly older than those with pure mucinous or pure Brenner tumor, with a mean age of 68 years. They are unilateral and most often have discrete Brenner and mucinous components, but in 30% the components are admixed. The

FIGURE 24.40. Brenner tumor. The transitional cell type is characterized by ovoid to spindle nuclei with prominent nuclear grooves, which resembles urothelium.

other clinical and pathologic features are similar to their pure counterparts (285).

Atypical Proliferative Brenner (Transitional Cell) Tumors

These rare neoplasms, also termed “atypical proliferative” or “borderline” transitional cell or Brenner tumor, or transitional cell or Brenner tumor “of low malignant potential,” present in patients whose mean age is 59 years. They are always unilateral and confined to the ovary. They are much larger than their benign counterparts, are usually cystic, and measure 10 cm to 28 cm with a mean diameter of 18 cm. Papillary or polypoid masses project into the cyst lumens, and there is usually a benign Brenner component present with a solid and fibrous cut surface. Microscopically, the intracystic papillary component is composed of transitional-type epithelium resembling low-grade noninvasive papillary transitional cell neoplasms of the urinary tract. Mucinous metaplasia may be present in the epithelium lining the papillae. Underneath the papillae and within the wall there may be solid areas of transitional epithelium with little intervening stroma (Fig. 24.41). Nearly all cases display areas of benign transitional cell neoplasm. The cytologic features are similar to those in benign transitional cell tumors, but occasionally significant atypia and mitotic activity are present. Among over 50 reported cases of atypical proliferative transitional cell tumors, there has been one local recurrence and no convincing evidence of malignant behavior. Accordingly, the term, “atypical proliferative transitional cell (Brenner) tumor” is preferred.

Malignant Transitional Cell Tumors (Malignant Brenner Tumors and Transitional Cell Carcinomas)

High-grade serous carcinomas may have focal areas that display features resembling transitional cell carcinoma. Nearly all tumors that have historically been classified as ovarian transitional cell carcinomas (TCC) are now regarded as high-grade serous carcinomas with transitional-like features by most but not all experts.

Some investigators have found that approximately 10% to 15% of advanced-stage ovarian carcinomas contain a transitional-like component; others have found that a transitional-like pattern predominates in 22% of advanced-stage ovarian carcinomas. In contrast, we have found only 3%

FIGURE 24.41. Atypical proliferative transitional cell (Brenner) tumor with expansile proliferation of transitional-type epithelium displaying mild to moderate cytologic atypia.

of advanced-stage serous carcinoma were classifiable as TCC. Some investigators have defined 2 clinicopathologic types of malignant transitional cell tumor: malignant Brenner tumor, in which a benign or atypical proliferative Brenner component is identified, and TCC, in which no benign or atypical proliferative Brenner component is identified.

Clinical and Operative Findings

Malignant Brenner tumors comprise 1% of ovarian carcinomas and occur at a mean age of 63 years, while TCCs present at a mean age of 56 years. The size of malignant Brenner tumors ranges up to 25 cm with a mean diameter of 14 cm. Among stage I tumors, 16% are bilateral. The stage distribution is as follows: stage I, 64%; stage II, 12%; stage III 18%; stage IV, 6%. In contrast, the majority of TCC present in advanced stage. The mean size of TCC is 10 cm.

Gross Findings

The gross appearance of TCC is similar to high-grade serous carcinoma that is typically solid and cystic. The cysts may exhibit polypoid, friable mural nodules, and the cyst fluid is watery or mucinous. Hemorrhage and necrosis may be prominent, and half have foci of gritty calcification. In the malignant Brenner tumor, the benign Brenner component may be identifiable as a solid fibrous nodule within a cyst wall. Sometimes malignant Brenner tumor is completely solid. Serous carcinomas that have a transitional cell component have the gross features of serous carcinoma.

Microscopic Findings

The histologic patterns of TCC are often mixed with other types of carcinoma, most often serous. Approximately 10% of ovarian carcinomas containing the TCC pattern are said to be pure. More than 50% of the tumor should display the patterns of TCC for a diagnosis of TCC. A diagnosis of malignant Brenner tumor is warranted when a benign or atypical proliferative Brenner component is identified within or is contiguous with the tumor.

The characteristic microscopic feature is thick, blunt, and often elongated papillary folds with fibrovascular cores, lined by transitional-type epithelium resembling urothelium. The papillae often appear to arise from a cyst wall with a similar lining of stratified and atypical transitional cells. A solid pattern is present in about half the cases. Stromal invasion is present and characterized by haphazard infiltrative growth of epithelium at the base of the papillae into the cyst wall, or extensive areas of solid epithelial proliferation with scant or no fibrovascular support. Another architectural pattern of malignant Brenner tumor is characterized by a solid tumor resembling benign Brenner tumor but the epithelial nests are more angulated and have a disorderly growth pattern which appears invasive (Fig. 24.42). In our experience, this latter pattern is the most common pattern of malignant Brenner tumor. In TCCs, cytologic atypia is usually prominent. High-grade pleomorphic nuclear features and bizarre giant cells occur in about one-third, further supporting the opinion that these tumors are transitional-like variants of serous carcinoma. In addition, malignant Brenner tumors, like their benign counterparts, often have prominent stromal calcification which is usually spiculated, in contrast to TCCs in which calcification is less common and more often psammomatous as in serous carcinomas.

Clinical Behavior

Limited data suggesting that TCC is more chemosensitive than serous carcinoma have not shown a prognostic difference independent of stage and volume of residual disease. TCC is clinically different from malignant Brenner tumor. TCC presents in

FIGURE 24.42. Malignant Brenner tumor characterized by small variably sized nests of transitional-type cells with an infiltrative pattern.

advanced stage, while most malignant Brenner tumors present in stage I. TCC is a variant of high-grade serous carcinoma and thus is a Type II tumor. This is supported by similar clinical and pathologic features between these 2 types of ovarian carcinoma, and an immunophenotype that more closely resembles serous carcinoma rather than TCC of the urinary tract. In contrast, malignant Brenner tumor has features of a Type I tumor (see Pathogenesis, earlier in this chapter).

Squamous Tumors

Epidermoid cysts comprise 1.4% of ovarian epithelial tumors. They are lined by squamous epithelium and lack teratomatous elements (286). Pure invasive squamous cell carcinoma is very rare, comprising 0.4% of ovarian carcinomas. In a series of 18 cases, endometriosis was found in 7 cases, and no underlying lesion was found in 11 cases. Invasive squamous cell carcinoma in the ovary is most commonly due to malignant transformation of a mature cystic teratoma; in such cases, the tumor is classified as a germ cell tumor with malignant transformation. Rarely, metastatic disease from the uterine cervix is the source of squamous cell carcinoma in the ovary.

The majority of patients with primary ovarian squamous cell carcinoma present with advanced-stage disease and die within 1 year. Although data are limited, this entity appears to confer a significantly worse prognosis than either high-grade serous carcinoma or squamous cell carcinoma arising in a mature cystic teratoma.

Mixed Epithelial Tumors

According to the WHO, the presence of 2 epithelial cell types in an ovarian epithelial neoplasm, each comprising at least 10% of the tumor, warrants a designation of a mixed epithelial tumor. Nonetheless, as mixed epithelial tumors are by necessity a heterogeneous group, it is more convenient and of no significant clinical import to ignore the minor components and classify tumors based solely on the predominant component, unless the minor component is malignant in an otherwise benign tumor, or is of a higher grade than the remainder of the tumor. As the prognosis for all cell types is essentially the same when stratified by stage, it is preferable to designate tumors based on the predominant component. Serous and endometrioid differentiation may occur together. In particular, poorly differentiated serous and endometrioid carcinomas often display overlapping

features, and at times, assignment to one or the other group is arbitrary and varies among observers. As discussed earlier, it has been suggested that there is no clinical or molecular basis for separating high-grade serous and endometrioid carcinomas. Many experts believe that these tumors are preferably classified as serous, reserving endometrioid for those tumors that display easily recognizable and characteristic features of eutopic endometrioid adenocarcinomas. Similarly, endometrioid and clear cell differentiation are not infrequently mixed. A mucinous component is often observed in benign transitional cell neoplasms (see above, mixed transitional cell-mucinous tumors).

Undifferentiated Carcinoma

Undifferentiated carcinomas show no readily identifiable features of any of the cell types of ovarian surface epithelial neoplasms. Therefore, any element of glands, papillae, or psammoma bodies removes a tumor from this category. Solid carcinomas with rare foci of glands or papillae are preferably classified as serous, although a few experts include such tumors in the undifferentiated category.

There are 4 types of primary ovarian undifferentiated carcinoma, referred to as follows: undifferentiated carcinoma not otherwise specified (NOS), non-small-cell neuroendocrine carcinoma, the hypercalcemic type of small cell carcinoma, and the pulmonary type of small cell carcinoma. When strict pathologic criteria are employed for these diagnoses, all types are very rare, together comprising less than 1% of invasive carcinomas. In the Washington Hospital Center series of 530 carcinomas (Table 24.11), there was a solitary case (0.2%) of undifferentiated small cell carcinoma (hypercalcemic type). In all cases when a diagnosis of undifferentiated carcinoma is considered, it is very important to exclude metastatic tumor, particularly from the lungs.

Although data are limited, undifferentiated carcinoma NOS appears to be more common than the other 3 types. The small cell type of undifferentiated carcinoma associated with hypercalcemia is the most common type of undifferentiated carcinoma in women under age 40 years. The usual type of undifferentiated carcinoma shares most clinical and pathologic features with high-grade serous carcinoma and therefore is probably a variant of this type. The mean age at presentation is 60 years and nearly all present in stages III and IV. Tumors are composed of solid sheets of large pleomorphic cells with high-grade nuclear features, and usually with abundant cytoplasm that is often eosinophilic. Overall, 22% survive 5 years, but only 14% of patients with stage III and IV disease survive 5 years. Although overall survival appears somewhat worse than that for serous carcinoma, data on this rare tumor are quite limited and when stratified by stage, patients with undifferentiated carcinoma do not have a significantly worse prognosis than those with high-grade serous carcinoma.

Non-small-cell neuroendocrine carcinoma is usually associated with another cell type of surface epithelial carcinoma, most often mucinous carcinoma, and therefore is best classified according to the better-differentiated component. Undifferentiated small cell carcinoma associated with hypercalcemia is a distinctive neoplasm occurring in young women with a mean age of 23. There is a characteristic microscopic pattern with sheets of small cells with interspersed follicle-like spaces. It is associated with a poor prognosis.

Malignant Mixed Mesodermal Tumor (Carcinosarcoma)

Although they were previously thought to be rare, carcinosarcomas comprise about 6.4% of ovarian carcinomas in the United States (Table 24.11) and 2.5% in Thailand (287). The mean age

at diagnosis, 64 to 66 years, is higher than that for serous carcinoma. These tumors are typically large, ranging from 15 cm to 20 cm in diameter. The stage distribution is identical to that of serous carcinoma. The morphology is similar to its uterine counterpart. The characteristic microscopic feature is an intimate admixture of malignant epithelial and stromal elements. The malignant epithelial element is most commonly a high-grade serous or endometrioid carcinoma, but can be of any of the surface epithelial cell types of ovarian tumors. The stromal component usually contains sheets of hyperchromatic rounded to spindled cells with marked nuclear atypia and a high mitotic index. Heterologous elements, most commonly cartilage, osteoid, and rhabdomyoblasts, are commonly found and, as in the uterine counterpart, their frequency depends on the diligence with which they are sought. Occasionally, a tumor that is otherwise a typical carcinoma has a small focus of malignant stroma. Although there are few published data on such tumors, they are classified as malignant mixed mesodermal tumors (MMMTs). Immunohistochemical stains for epithelial markers are often positive in the sarcomatous component, and their behavior and patterns of spread are similar to high-grade serous carcinomas. Like endometrial carcinosarcomas, the majority have been demonstrated to be monoclonal. These observations indicate that these tumors should be classified as metaplastic carcinomas like their uterine counterparts, and accordingly represent a Type II tumor (see Pathogenesis, earlier in this chapter). In the older literature, MMMTs were considered aggressive, rapidly fatal tumors with a median survival of approximately 1 year, but more recent data suggest that with cisplatin and either a taxane or ifosfamide therapy, survival rates approaching those for serous carcinoma can be achieved (288). When stratified by stage, some but not all studies have shown that the prognosis does appear to be worse than that for serous carcinoma. Most but not all studies have shown that, like their uterine counterpart, the presence of heterologous elements does not influence prognosis.

Sarcomas

Although primary, pure, or mixed sarcomas of the ovary are very uncommon, they constitute a heterogeneous group with 4 different types of neoplasms: endometrioid stromal sarcoma, adenosarcoma, sarcoma arising in a mature teratoma, and miscellaneous soft tissue sarcomas. Most carcinosarcomas are no longer considered sarcomas (see Malignant mixed mesodermal tumors, above). All of these tumors are extremely rare. Sarcomas arising in teratomas are classified as germ cell tumors with secondary malignant transformation.

Endometrial Stromal Sarcoma

Endometrioid stromal sarcoma (ESS; comprising the group of tumors formerly known as low-grade endometrial sarcoma) is an extremely rare primary ovarian neoplasm that is morphologically identical to its uterine counterpart. Among approximately 27 reported cases, 63% have been closely associated with endometriosis from which the tumor probably arises. The mean patient age is 52 years. The mean tumor size is 10 cm. Over 70% present in advanced-stage (FIGO II–III). Since primary uterine ESS is often slow growing and prone to late recurrence, it is important to consider the possibility of metastatic tumor from a uterine primary, even if the patient has had a hysterectomy in the remote past. Ovarian sex cord-stromal tumors with a predominant spindle cell component, including cellular fibroma, thecoma, and poorly differentiated Sertoli-Leydig cell tumor, are also important differential diagnostic considerations, and rarely an ovarian stromal tumor will have spindle cell patterns that are virtually identical to ESS. The behavior appears to parallel that of advanced-stage uterine ESS, although data are limited.

Mullerian Adenosarcoma and “Aggressive Endometriosis”

Mullerian adenosarcoma of the ovary is very rare. It is morphologically similar to its uterine counterpart. Nearly 60 cases have been reported (289). The mean age is 54 years and the mean tumor size is 14 cm. Sixty-five percent present in FIGO stage I. Nearly all cases are unilateral. Grossly, the majority are predominantly solid with some cystic areas, and 10% are predominantly cystic. The characteristic microscopic feature is periglandular stromal condensation with atypia and mitotic activity in these hypercellular areas of stroma. Leaflike processes of stroma covered by a single layer of benign epithelium is another characteristic pattern. About 15% have sex cord-like elements and 30% have sarcomatous overgrowth. In the largest series (289), among 40 cases, 9 tumors were considered high-grade (moderate or severe atypia and/or 10 or more mitoses per 10 hpf in the most active areas) and 31 were low-grade. Sixty-three percent of stage I tumors recurred. The 5-year recurrence free survival was 45% for women with low-grade stage I disease and 25% for women with high-grade stage I disease. The overall 5-year survival is about 65%. Interestingly, among 40 patients, 2 had small synchronous adenosarcomas that appeared to be independent: one in the endometrium and one arising in appendiceal endometriosis.

Rarely, histologically benign endometriosis appears infiltrative to the surgeon and/or displays perineural and vascular invasion. The stroma can be cellular but there is no atypia and mitotic activity is very low. It can prove difficult to resect and consequently may display low-grade malignant behavior. This may be a form of low-grade adenosarcoma and has been referred to as “aggressive endometriosis.” It has also been suggested that these are low-grade endometrial stromal sarcomas with endometrioid glandular differentiation. There are no large series of this entity and it is therefore poorly understood.

Tumors of the Fallopian Tubes

Benign Tumors

The most common benign tumor of the fallopian tube is adenomatoid tumor, also referred to as benign mesothelioma because of its histogenesis, which is now known to be mesothelial. These are nearly always incidental findings, typically 1 cm to 2 cm and often microscopic, and within the myosalpinx. They are firm and yellowish on cut section. Microscopically they display interanastomosing tubules and glands with no atypia or mitotic activity. The cytoplasm is eosinophilic and vacuolated. Of note, a small biopsy of a diffuse malignant mesothelioma can have an identical histological appearance. This is of little practical concern, as peritoneal mesotheliomas in women are exceedingly rare; we diagnosed 2 malignant peritoneal mesotheliomas during the same period as our consecutive series of 530 ovarian carcinomas over a 20-year period.

The tubal mucosa rarely gives rise to benign papillomas, SBTs and so-called metaplastic papillary tumor of pregnancy. This latter lesion is an epithelial metaplasia rather than a neoplasm. SBT more often arises within the leaves of the broad ligament. The myosalpinx, as it is composed of smooth muscle, occasionally gives rise to small leiomyomas. Occasional examples of tubal adenomyomas probably represent endometriosis with prominent smooth muscle proliferation. The peritoneal-lined serosal surface, in addition to adenomatoid tumor (see above), also may produce mesothelial/peritoneal cysts. When a mesothelial cyst is multiloculated, the pathologist may consider the possibility of so-called multicystic mesothelioma. However, this latter entity is exceedingly rare and probably not truly neoplastic. A diagnosis of cystic adhesions or multiloculated mesothelial/peritoneal cyst is most appropriate.

Female adnexal tumor of probable wolffian origin (FATWO) is a rare epithelial neoplasm that is usually found within the broad ligament and probably arises paratubally from mesonephric remnants. It is generally benign; however, it may recur. Several late recurrences and rare fatalities have been reported.

Malignant Tumors

High-grade Serous Carcinoma

The most common tubal malignancy is high-grade serous carcinoma, that is clinically and pathologically identical to high-grade serous carcinoma of the ovary and peritoneum. Until recently, carcinoma of the fallopian tube was thought to be rare, comprising less than 1% of gynecological malignancies. Over the past decade, evidence has been accumulating that a significant proportion of apparent ovarian and peritoneal high-grade serous carcinomas are associated with serous tubal intraepithelial carcinoma (STIC). STIC is usually fimbrial and is now felt by many but not all experts, to be the source of a majority of these tumors. This is discussed in greater detail earlier in this chapter (see Pathogenesis; and High-grade serous carcinoma).

There are very rare reports of clear cell and endometrioid carcinomas of the fallopian tube. Since these tumors, when ovarian, arise in endometriosis, tubal examples presumably arise in endometriosis as well. Several studies have shown that STIC is specifically associated with serous carcinomas (260,290), so that a tubal epithelial origin of clear cell or endometrioid carcinoma is unlikely.

Tubal carcinosarcomas (malignant mixed müllerian tumors) rarely occur and are classified as variants of high-grade serous carcinoma like their ovarian counterparts. Other types of sarcoma are exceedingly rare.

PROGNOSTIC FACTORS

Universally accepted prognostic factors for patients with ovarian cancer are FIGO stage, which reflects a combination of tumor size and disease distribution, and, in patients with stage IIIC and IV disease, volume of residual disease after surgical staging.

The issue of the prognostic importance of cell type and grade is complex because these features are interdependent, making it difficult to analyze them separately. Moreover, grade is poorly reproducible among pathologists. The vast majority of serous and clear cell carcinomas are high-grade regardless of the grading system used, while endometrioid and mucinous carcinomas are more often low-grade (263,291,301). As noted above (see Endometrioid Adenocarcinomas) overlap of both morphological and molecular features between high-grade endometrioid and high-grade serous carcinomas has led most authorities to assign the vast majority of gland-forming or near-solid cytologically high-grade ovarian carcinomas to the serous category, to the degree that “true” high-grade endometrioid carcinomas are uncommonly diagnosed.

Tumor Stage

Most patients with advanced-stage disease will have serous tumors. There is variability in survival for patients with the same FIGO stage, reflecting both the variability in completeness of staging (particularly for early-stage disease) and the variable biology of different histologic subtypes of ovarian cancer. SEER data suggest that 5-year relative survivals are 89% for patients with stage I disease, 45% for those with stage IIIa disease, 35% for those with stage IIIC disease, and 18% for those with stage IV disease. Ten-year figures decrease to 84%, 31%, 23%, and 10%, respectively (292). (Figure 24.43).

Prognostic Variables in Early-Stage Disease

About one-third of patients present with stage I or II epithelial ovarian cancer (Table 24.1). Prognostic factors are particularly important in stage I disease because chemotherapy can be withheld for the subsets with best prognosis (see Fig. 24.44). Vergote et al. performed a large retrospective study using an international database of over 1,500 women with stage I invasive epithelial ovarian cancer to identify the most important prognostic variables. Routine peritoneal washings and lymphadenectomy were not performed, but palpable nodes were sampled. Twenty-eight percent of the tumors were serous, 27% were mucinous, 23% were endometrioid, 12% were clear cell, 3% were undifferentiated, and 6% were mixed. Chemotherapy administration was variable. The overall actuarial 5-year survival was 83% (disease-free survival 80%) (293,294). Multivariate analysis identified grade as the most powerful prognostic indicator of disease-free survival: patients with poorly versus well-differentiated disease on a 3-grade system had an 8.89 fold increased risk of recurrence. Other significant factors included rupture before surgery (Hazard Ratio (HR) 2.65); rupture during surgery (HR 1.65); and age (HR increased by 1.02 per year). Histologic subtype did not have independent prognostic significance. Size was not prognostic; low-grade early-stage tumors may be very large. A multivariable analysis of prognostic factors for recurrence in 2 GOG trials of women with surgically staged stage I and II disease, GOG #95 and GOG #157, identified 4 independent predictors: age > 60 years (HR 1.57), stage II (HR 2.7 versus stage IA or IB), grade 2 (HR 1.84 versus grade 1) or grade 3 (HR 2.47 versus grade 1), and positive cytology (HR 1.72). The 31% of the patients with stage II disease accounted for the majority of the recurrences (295).

Histologic Subtype

As noted above, the distribution of cell types in early-stage disease is very different from the distribution in advanced-stage disease. Most advanced-stage cancers are serous, whereas less than a third of early-stage cancers are serous (296). Endometrioid and clear cell cancers tend to present in an early-stage as

FIGURE 24.44. Standard Management of Stage I/II Ovarian Carcinoma.

a single mass. Serous histology has been reported to be a poor prognostic factor in stage I disease, especially in patients who have not been comprehensively staged (297). From 4% to 25% of patients with apparent stage I ovarian cancer will have nodal involvement when lymph nodes are pathologically examined; the risk for lymph node involvement correlates with histology (higher risk with serous and clear cell tumors) and grade (higher risk with higher grade).

Stage I clear cell carcinoma historically has been believed to be associated with a significantly worse outcome than the other cell types. However, several recent large recent series have not confirmed this (295,297–299). While advanced-stage mucinous tumors have a very poor prognosis, stage I mucinous tumors are generally low-grade, and have a good prognosis.

Grade

Despite the caveats mentioned above about interplay between histologic subtype and grade and about lack of reproducibility of grade, grade is associated not only with the likelihood of lymph node involvement in apparent stage I disease, but with the likelihood of recurrence in fully staged patients. From FIGO data for surgically staged patients (296) the overall 5-year survivals are 92%, 85%, and 79% for stage I grade 1, 2, and 3 tumors, respectively. Stage IA and IB grade 1 carcinomas have disease-specific survival rates as high as 97% in the absence of any adjuvant therapy (291).

Issues are less clear in more advanced-stage disease. Two recent large studies with uniform expert pathology, a Canadian population-based study of 575 patients with stage I–III optimally debulked patients (291), and a review of 1,895 stage III patients from a compilation of Gynecologic Oncology Group studies (300), review found that grade was not an independent prognostic factor in multivariate analysis.

A recently proposed binary grading system for serous carcinoma separates the majority of high-grade serous tumors from a small distinctive group of low-grade serous carcinomas (301).

Low-grade serous carcinoma, as currently defined by this system, is not simply a different grade of serous carcinoma (291,301); it is a distinctively different disease with specific molecular alterations, histopathology and clinical behavior (198). The low-grade group includes invasive MPSC as discussed earlier in this chapter (see section “Pathology”).

Surgical Prognostic Factors

Capsular rupture and malignant ascites are associated with worse outcomes, and are incorporated into stage. Tumor size is not prognostic. Uncertainty remains regarding adhesions. No problem regarding staging exists when the surgeon encounters discrete implants separate from the primary tumor or when solid tumor is found invading adjacent structures. However, more often, apparently benign adherence of a cyst to adjacent structures, in the absence of metastatic implants or obvious direct tumor extension, is found. There is an older body of evidence suggesting that such “benign” adhesions, when dense, are associated with a relapse risk equivalent to stage II, and that these patients should be considered to have stage II disease (302). Adherence is judged to be dense when so described by the surgeon, when sharp dissection was required to mobilize the tumor, when a raw area was left in the place of adherence, or when cyst rupture resulted from dissecting the adhesions free. Some clinical trials have advanced the stage of nonmetastatic but densely adherent tumors to stage II. However the retrospective international study of Vergote et al. (303) as well as a review by Seidman et al. (304) failed to identify dense adhesions as an independent prognostic factor. Adhesions are not used by the GOG to “upgrade” apparent stage I patients without histologic confirmation of disease.

CA125 Levels

A report analyzing data from 600 surgically staged (including lymphadenectomy) FIGO stage I epithelial ovarian cancer patients found preoperative serum CA-125 ≥ 30 U/mL to be an

independent predictor of decreased survival (HR 2.7). Clear cell and mucinous tumors had somewhat lower preoperative CA-125 levels. The only independent predictive factor other than CA-125 was age greater than 70 years (HR 2.6) (305).

Prognostic Variables in Stage III/IV Disease

Volume of Residual Disease After Surgery

As discussed more extensively in Section “Surgery,” the volume of residual disease following cytoreductive surgery is directly correlated with survival for both stage III and stage IV disease (see Figs. 24.15 and 24.16). Most series have focused on the size of the largest residual mass, and not the total number of lesions, but the number of residual masses may be an important prognostic factor as well. There is, of course, a correlation between volume of disease before surgery and residual disease remaining after surgery. While patients with stage IIIC disease who are without residual disease after surgery do better than patients with stage III C disease who have macroscopic residual disease, they still have a significantly worse prognosis than patients with stage IIIA disease (who are more likely to have low-grade tumors) (306). Women with a diagnosis of stage IIIC disease based solely on lymph node involvement have a better prognosis than those with a diagnosis of stage IIIC disease based on bulky upper abdominal metastasis (307).

Histologic Subtype and Grade in Advanced Disease

In advanced-stage disease, mucinous and clear cell histologies are associated with a significantly worse prognosis, possibly because of chemotherapy resistance. Advanced-stage endometrioid tumors are associated with a better prognosis than advanced-stage serous tumors. One retrospective series, which included patients with stages IIC–IV disease treated with paclitaxel/platinum following cytoreductive surgery showed median overall survivals of 121 months for low-grade serous tumors, 15 months for mucinous tumors, 64 months for endometrioid tumors, 29 months for clear cell tumors, and 45 months for a category including high-grade serous, unspecified and undifferentiated carcinomas (308). Not all series show such dramatic differences in prognosis for women with low-grade versus high-grade serous carcinomas. Seidman et al. compared 2 binary grading systems for serous carcinomas, and found that 5-year survival for women with high-grade versus low-grade stage III disease was 35% versus 39% using one system and 34% versus 56% using another (309). An analysis of tumors of women treated on GOG 158 (optimally debulked stage III disease) found that using the two-tier system developed at the MD Anderson Cancer Center, 8.7% of women had low-grade disease with a median progression-free survival of 45 months versus 19.8 months for the 91.3% of women with high-grade disease. Three-year overall survival was 90.5% for those with low-grade disease versus 67.6% for those with high-grade disease. Using FIGO grading the median progression-free survival for grade 1, 2, and 3 tumors was 37.5, 19.8, and 20.1 months, respectively (310).

Grade and stage are confounded: low-grade serous carcinoma (invasive MPSC) is more likely to be stage IIIA or IIIB as compared to high-grade serous carcinoma (Type II), which is nearly always presents as stage IIIC disease. In addition, low-grade serous tumors occur in younger women who tend to have fewer comorbidities (311). Regardless of the grading system used, low-grade serous tumors (Type I) make up only a small fraction of stage III serous tumors (less than 10% using the MD Anderson grading system). It seems likely, given the different molecular alterations seen in Type I versus Type II serous tumors, that in the future different systemic therapies will be used for each type. However, at this time, although some reports

suggest that cytotoxic chemotherapy is less effective against advanced-stage low-grade tumors (312), there are no good data to suggest appropriate alternative therapy.

CA-125 Levels in Advanced Disease

Although not all patients with advanced ovarian cancer have an elevated serum CA-125 level, serum levels of CA-125 generally reflect volume of disease. Prechemotherapy CA-125 levels have been shown on univariate analysis to be of prognostic significance, but on multivariate analysis, they are usually not an independent prognostic factor owing to their association with volume of disease (313). Postoperative CA-125 levels appear to have greater prognostic significance, and have been reported to be of independent prognostic significance in patients with or without residual disease. Decline of CA-125 with chemotherapy is also prognostic. In one study, normalization of CA-125 (level less than 35 U/mL) after the third cycle of treatment was associated with a median overall survival of 42 months compared to a median survival of 22 months for those whose CA-125 did not normalize. This association held true even within the subgroup of optimal microscopically debulked patients (314).

Other Prognostic Factors

Age is a strongly adverse prognostic factor in most studies. This may partially reflect comorbidities and the inability of older patients to tolerate intensive therapy, but nonetheless older patients are more likely to present with advanced-stage and high-grade disease. Poor performance status and an increased number of patient-reported symptoms, particularly lower extremity edema, are associated with worse outcomes (315). Perioperative infection has been reported to be an independent risk factor for poor outcomes, with an associated decrease in median survival by nearly 2 years (316). High maximum standardized uptake (SUVmax) of primary tumor on positron emission tomography (PET) scanning is correlated with stage (increased in higher stage tumors) and histology (increased in serous tumors), and is associated with shorter survival (317). Thrombocytosis has been reported to be associated with advanced disease and shortened survival (318). In the United States, African American race is associated with worse outcomes, and this disparity has been increasing over time; differences in access to care may account for a large portion of this finding, as studies at single institutions with consistent treatment of patients or on clinical trials do not show significant differences in outcomes by race (319–321). *BRCA1* and *BRCA2* mutations have been reported in most, but not all, series to be associated with both an improved survival and a higher response rate to platinum-based therapies (322–325). Microarray-based gene expression profiles with prognostic significance are being developed, but none have yet come into clinical use (326,327).

EARLY-STAGE (I AND II) OVARIAN CANCER

Approximately 25% of women with ovarian carcinoma present with stage I or II disease. Survival by stage is presented in Figure 24.43. An algorithm for standard management of early-stage disease is shown in Figure 24.44. Unlike advanced-stage ovarian cancers, which are usually high-grade serous tumors, around a third of early-stage tumors are low-grade, and mucinous and endometrioid tumors are about as common as serous tumors (Table 24.12). Clear cell tumors make up over 10% of early-stage disease (294,296).

Table 24.12 Relationship between Histology and Stage in Ovarian Cancer

	IA (n = 749) (%)	IIIC (n = 2,424) (%)
Serous	21	68
Mucinous	33	7
Endometrioid	24	11
Clear cell	14	4
Undifferentiated	2	6
Mixed	6	4

Surgical Therapy for Early-Stage Ovarian Carcinoma

Surgery will be curative for most patients with early-stage ovarian cancer. The optimal surgical procedure for most epithelial ovarian carcinomas is removal of the uterus along with both fallopian tubes and ovaries and complete surgical staging. This is discussed in more detail in section “Surgery.” There are a few situations in which full staging is not always needed, such as incompletely staged borderline ovarian carcinomas and grade 1 mucinous tumors (328,329). The general advantage of surgical staging in early ovarian cancer is that chemotherapy can sometimes be omitted in a fully staged patient.

Fertility Preservation

In the younger patient who wishes to retain her childbearing potential and who appears to have a curable cancer (i.e., a localized tumor with mucinous, endometrioid, or low-grade serous histology), it is appropriate to preserve the uterus and the contralateral ovary. Any abnormalities in the remaining ovary should be biopsied during surgery and sent for frozen section. If the frozen section is ambiguous as to whether the tumor is benign, borderline, or malignant, or if there is doubt about the extent of the disease, final pathology should be awaited and a two-step surgical approach employed. If both ovaries contain invasive tumor on frozen section ovarian preservation is usually not indicated.

Recommendations (330): FIGO IA, GI + II, serous, mucinous, endometrioid → Fertility sparing surgery

FIGO IA, clear cell cancer → Consider fertility sparing surgery

FIGO IC, GI + II, serous, mucinous, endometrioid → Consider fertility sparing surgery

FIGO IC, clear cell cancer → No fertility sparing surgery

FIGO IA + IC, GIII → No fertility sparing surgery

Postoperative Follow-up for Stage I Ovarian Carcinoma

As described above, patients with stage IA and IB grade 1 carcinomas have been reported to have disease-specific survival rates as high as 97% in the absence of any postoperative therapy.¹ Early GOG trials similarly showed that overall, patients with stage IA or IB and grade 1 or 2 disease had a 5-year disease-free survival rate (DFS) of 91% and a 5-year overall survival rate of 94% with surgery alone (331). Other patients with early-stage disease are considered to have a risk of recurrence high enough to warrant adjuvant therapy. However, the benefit of

such treatment has been difficult to prove because the number of patients with higher grade early-stage disease is small (so trials are difficult to complete) and the overall risk of recurrence is not that great (so large trials are needed). Published trials have included multiple histologic types with very different biology and variable staging, and generally have lacked the power to show interactions between treatment and grade or histologic subtype. In addition, treatment at recurrence may be curative for a small number of patients who did not receive initial adjuvant treatment.

Radiotherapy for Early-Stage Ovarian Cancer

External Beam Therapy

Early small randomized trials suggested that pelvic radiotherapy compared to observation for early-stage ovarian cancer reduced the rate of relapse in the pelvis, but had no impact on overall recurrence rate or survival because relapses occurred throughout the peritoneal cavity (332). Interest turned to abdominopelvic radiotherapy in the early 1980s after investigators from the Princess Margaret Hospital in Canada published results of a small study showing that for women with incompletely staged IB, II, or III optimally debulked ovarian cancer randomized to pelvic radiotherapy plus whole abdominal radiotherapy (WAR) had a survival advantage over those randomized to pelvic radiotherapy followed by chlorambucil (333). However, subsequent trials did not confirm this finding (334,335). Investigators at the M. D. Anderson Cancer Center randomized 156 patients with FIGO stage I, II, or III disease to melphalan alone versus abdominopelvic radiotherapy, and found similar relapse-free survival for both treatments in women with stage I or stage II disease (336). A later small trial published in 1994 showed a trend towards superiority of cisplatin/cyclophosphamide chemotherapy over WAR in women with high-risk early-stage disease (337).

Currently, radiation is rarely used as primary therapy for ovarian cancer, but interest in this approach remains. Given that pelvic radiotherapy can decrease local relapse, it is possible that the addition of radiotherapy to chemotherapy could improve disease control in some patients, such as those with bulky stage II disease, positive pelvic margins (pelvic sidewall or colon) or chemotherapy-resistant subtypes of disease, such as clear cell tumors. Swenerton et al. recently reviewed data on 703 women from Canada with no macroscopic residual disease after surgery who underwent platinum-based chemotherapy with or without sequential abdominopelvic radiotherapy. Among women with stage I or stage II clear cell, endometrioid, or mucinous histology, the addition of radiotherapy was associated with a 43% decrease in overall mortality (338). No benefit was seen for those with stage III disease or tumors of serous histology. The most common late side effect was chronic GI toxicity, with 41/351 women having chronic grade 2 or higher GI toxicity. A subsequent analysis from the same group looked only at clear cell carcinomas, and suggested a benefit specifically for stage IC and stage II disease (339). It seems possible that similar benefit and less toxicity could be seen with pelvic radiotherapy alone rather than abdominopelvic radiotherapy, and hopefully future trials will address this issue.

Radiocolloid Therapy

Since transcoelomic spread is the main route of dissemination of ovarian cancer, the intraperitoneal instillation of radiocolloids, which deliver high doses of radiation to the peritoneal surfaces, was historically used for early-stage disease. Intraperitoneal ³²P, which penetrates only 2 mm to 3 mm, was the isotope most commonly administered. Therapy was abandoned when

randomized data suggested better results with chemotherapy. In addition, a randomized comparison of ^{32}P versus observation did not show any decrease in the risk of relapse or improve survival in patients with more advanced-stage disease who had a surgically confirmed complete remission (340).

Chemotherapy for Early-Stage Ovarian Cancer

As shown in Figure 24.44, postoperative chemotherapy is usually recommended for patients with high-grade stage IA or IB tumors and most tumors of stage IC or higher. But it must be appreciated that we do not have strong evidence that such treatment improves overall survival. Randomized trials including platinum-based chemotherapy in early-stage ovarian cancer are summarized in Table 24.13. While individual trial results vary somewhat, as a group they have shown fairly consistent improvement in disease-free survival for postoperative chemotherapy versus observation or radiotherapy. However, the only clear demonstration of an overall survival benefit in the treatment of early-stage ovarian cancer comes from a joint analysis of 2 large European trials (the ACTION and ICON-1 trials), which together randomized 923 patients with early-stage disease to receive either platinum-based chemotherapy or no initial adjuvant treatment. Results of a pre-planned combined analysis indicated a statistically significant improvement in both disease-free survival (HR 0.64) and overall survival (HR 0.67) with adjuvant platinum-based therapy (Fig. 24.45) (341). Yet, even these results are not considered definitive proof of a benefit from chemotherapy in early-stage disease

because comprehensive surgical staging was not required for entry into these trials. In a retrospective subset analysis of the ACTION trial, the patients with optimal staging had no benefit from chemotherapy, raising concern that the overall positive results reflected the benefit of chemotherapy in women with low-volume stage III disease (341,342). However, only 151 patients were optimally staged, which is too few to provide statistical power for firm conclusions about the benefit of chemotherapy in this subgroup. Neither tumor grade nor histologic cell type predicted for relative benefit from treatment.

It has been suggested that the discrepancy between the benefit in disease-free survival and lack of benefit in overall survival seen in several of the randomized early-stage chemotherapy trials results from increased salvage rates for chemotherapy in patients who recur after observation or intraperitoneal ^{32}P . In an early Italian (Gruppo Interregionale Collaborativo in Ginecologia Oncologica; GICO) trial randomizing women to chemotherapy versus no adjuvant therapy, 1 of 7 women (14%) who relapsed after adjuvant chemotherapy was alive at the time of reporting, whereas 6 of 14 (43%) who relapsed after observation were still alive (343). However, most patients whose cancer recurs will die of their disease. Investigators at the Royal Marsden Hospital examined the salvage rate after relapse in their series of prospective observation for patients with stage I disease (344). Sixty-one (31%) of 194 patients relapsed at a median of 17 months (range, 6 months to 15.7 years), and 55 of them received platinum-based chemotherapy at the time of relapse. Progression-free survival at 5 years after relapse was 24%. In line with current thinking, although clear cell histology was not predictive for relapse, it was a poor prognostic factor for survival after relapse (345).

Table 24.13 Randomized Trials of Platinum-Based Chemotherapy in Early-Stage Ovarian Carcinoma

Author (yr)	N	Eligibility	Arms	Outcome
Vergote (1992) ⁵⁵⁰	347	Stage I, II, III without residual disease	^{32}P vs. Cisplatin	No difference in OS or DFS
Chiara (1994) ³³⁷	70	Stage IA/B Gr 3, Any IC, II	WAR vs. cisplatin/cyclophosphamide	5-yr OS 53% vs. 71% RFS 50% vs. 74% $p = \text{NS}$ Only 67% of patients completed WAR
Bolis (1995) ⁵⁵¹	83	Stage IA/B Gr 2/3	Observation vs. cisplatin	5-yr DFS 65% vs. 83% 5-yr OS 82% vs. 88%
Bolis (1995) ⁵⁵¹	152	Stage IC	^{32}P vs. cisplatin	5-yr DFS 65% vs. 85% 5-yr OS 79% vs. 81%
Trope (2000) ⁵⁵²	162	Stage I Gr 2/3 or Gr 1 aneuploid/clear cell	Observation vs. carboplatin	5-yr DFS 80% vs. 85% 5-yr OS 70% vs. 71% $p = \text{NS}$
Young (2003) ⁵⁵³	251	Stage IA/B Gr 3 or clear cell IC, II	^{32}P vs. cisplatin/cyclophosphamide	10-yr RFS 65% vs. 72% 10-yr OS: HR chemo 0.83 $p = \text{NS}$
ICON1 (2003) ³⁴²	477	Physician uncertain about need for chemotherapy	Observation vs. platinum-based chemotherapy	5-yr RFS 62% vs. 73% $p = 0.01$ 5-yr OS 70% vs. 79% $p = 0.03$
ACTION (2003) ¹⁵⁹	448	Stage IA/B Gr 2-3 All IC, IIA, and clear cell	Observation vs. platinum-based chemotherapy	5-yr RFS 68% vs. 76% $p = 0.02$ 5-yr OS 78% vs. 85% $p = \text{NS}$
Bell (2006) ³⁴⁶	427	Stage IA/B Gr 3 or clear cell All IC, II	Carboplatin/paclitaxel 3 cycles vs. 6 cycles	HR RFS 0.761 $p = \text{NS}$ 5-yr OS no difference
Mannel (2011) ³⁴⁹		Stage IA/B Gr 3 or clear cell, IC, II	Carboplatin/paclitaxel 3 cycles followed by observation vs. followed by weekly paclitaxel $\times 26$	5-yr RFS 77% vs. 80% $P = \text{NS}$

Note: DFS, disease free survival; Gr, grade; HR, Hazard Ratio; NS, not significant; OS, overall survival; RFS, relapse-free survival; WAR, whole abdominal radiotherapy.

International Collaborative Ovarian Neoplasm Trial 1 and Adjuvant Chemotherapy in Ovarian Neoplasm Trial: 2 parallel randomized phase III trials of adjuvant chemotherapy in patients with early-stage ovarian carcinoma. *J Natl Cancer Inst.* 2003;95:105–112, with permission.

Duration of Chemotherapy for Early-Stage Disease

The GOG #157 trial randomized 427 eligible patients with early-stage disease and unfavorable prognostic markers (stage IA or IB grade 3, clear cell, stage IC, and completely resected stage II) to receive either 3 or 6 cycles of carboplatin (area under the curve [AUC] 7.5)/paclitaxel (175 mg/m²) chemotherapy. Surgical staging was required, but 29 percent of patients had surgical procedures that were considered inadequate or inadequately documented. Overall 5-year survival did not differ by treatment arm (HR 1.02). Adjusting for initial FIGO stage and tumor grade, the recurrence rate was 24% lower for patients getting 6 cycles, but this difference was not statistically significant (relative hazard 0.761, 95% CI, 0.512 to 1.13; $p = 0.18$) (346). There was a slightly lower estimated benefit of 6 cycles of chemotherapy in the completely staged group (HR 0.66 for incompletely staged versus 0.796 for completely staged patients, but there was no significant evidence of heterogeneity in the treatment effect. Toxicity was increased with 6 cycles; in particular the rate of grade III and IV neurotoxicity was 11% versus only 2% with 3 cycles. A subsequent exploratory analysis showed that for the 97 women with serous tumors the risk of recurrence was significantly lower after 6 versus 3 cycles of chemotherapy; 83% versus 60% (HR 0.33; CI, 0.14–0.77, $p = 0.04$), whereas for those with nonserous tumors, including clear cell carcinomas, no benefit was seen. However, a test of homogeneity did not show a difference in treatment effect across cell types. The 5-year overall survival for women with serous carcinomas was 86% for those receiving 6 cycles of therapy and 73% for those receiving 3 cycles of therapy; this difference did not reach statistical significance. Grade was not associated with benefit from chemotherapy, but women with low-grade stage IA and IB tumors were not eligible (347). One interesting retrospective nonrandomized analysis suggested that 6 (vs. 4) cycles of chemotherapy for early-stage disease delayed, rather than eliminated, recurrences (348). The GOG conducted a subsequent trial (GOG #175) in the same patient-population randomizing 542 eligible women to either 3 cycles of carboplatin (AUC 6)/paclitaxel (175 mg/m²) or 3 cycles of the same regimen followed by maintenance therapy with weekly paclitaxel 40 mg/m² for 24 weeks. No significant

difference in recurrence free interval (HR 0.807) or overall survival was seen. Only 29% of subjects had serous histology, and their results did not differ from that of the overall population (HR 0.822) (349).

At this time it is recommended that patients with comprehensively staged stage IA or IB grade 1 epithelial ovarian cancer receive no postoperative chemotherapy (see Fig. 24.44). Patients with grade III or stage IC disease have a relapse risk of at least 20%, and this may be reduced with platinum-based chemotherapy, particularly for those with serous tumors. Treatment of stage IA or IB grade 2 cancers remains an area of uncertainty, particularly given the lack of reproducibility of pathologist-assigned grade. If a dichotomous (high vs. low) grading system for serous carcinomas comes into use, this issue may be resolved. Paclitaxel/carboplatin for 3 to 6 cycles is the usual treatment for early-stage high-risk disease. It is hoped that future data will better address which women with early-stage ovarian cancers actually derive benefit from therapy.

Early-Stage Clear cell Carcinoma

In general, clear cell carcinomas of the ovary are not graded; they are all considered “high grade” for treatment purposes, and have traditionally all been treated with adjuvant chemotherapy. As discussed below (Section “Clear cell and Mucinous Tumors”), more recent series do not suggest an inferior prognosis for women with early-stage clear cell cancers, but do suggest decreased chemotherapy sensitivity for advanced-stage clear cell carcinomas. It is possible that observation is appropriate for some stage IA clear cell carcinomas. A recent series described 20 patients with stage IA clear cell carcinoma; 4 underwent chemotherapy, whereas the remaining 16 patients received no additional therapy. No recurrence was observed in either group (350). Seven to 11% of patients with apparent early-stage ovarian clear cell tumors will have retroperitoneal lymph node involvement (351), compared to 28% for early-stage serous carcinomas (352).

As described above, retrospective reviews have shown that prognosis in early-stage clear cell carcinoma might be improved by the addition of radiotherapy, and hopefully future trials will address this issue.

Early-Stage Fallopian Tube Carcinomas

A small number of patients present with obvious early-stage disease in the fallopian tubes. They are frequently incidentally detected after surgery for nononcologic indication such as incontinence or after prophylactic salpingo-oophorectomy performed for cancer prevention in women with a *BRCA* mutation. These patients should be fully surgically staged. Most fallopian tube carcinomas are of high-grade serous histology. Prognosis of early-stage disease has been reported to be dependent on depth of invasion of the tumor into the fallopian tube. When controlled for stage and grade, they appear to have a prognosis similar to that of early-stage ovarian cancer (353). FIGO data suggest that patients with stage I disease have a 5-year overall survival of 81% (354). Since advanced-stage fallopian tube carcinomas appear to respond to platinum-based therapies in a manner similar to that of ovarian carcinomas, and since many cancers formerly thought to be ovarian cancers or primary peritoneal cancers are now believed to have originated in the fallopian tube, adjuvant chemotherapy is currently used for early-stage disease in most situations.

MANAGEMENT OF BORDERLINE TUMORS

Borderline (low malignant potential; LMP) tumors comprise 10% to 20% of ovarian malignancies, and most are serous or mucinous. They were first described by Taylor in 1929 and recognized by FIGO in 1971 as a distinct histologic subtype. Their histology is reviewed in detail in section “Pathology.” In general, patients with borderline tumors present at a younger age (on average 10 years younger), and have earlier-stage disease than women with invasive ovarian carcinomas. They also have a longer survival and a risk for late recurrences.

As discussed in the pathology section, current concepts suggest that borderline tumors are precursors to Type I invasive tumors; SBT are precursors to low-grade (not high-grade) serous tumors and MBTs are precursors to invasive mucinous tumors. SBT are more common than MBTs in the United States; in Asia, the rate of MBTs has been reported to be similar or higher than that of SBT (355). Approximately 75% to 80% of borderline tumors are diagnosed at an early stage. For practical purposes, all MBTs are early-stage. Even when SBT present with more advanced-stage disease, survival is prolonged. A review of borderline tumors entered into the NCI SEER database between 1988 and 1997 (when SEER stopped collecting data on ovarian borderline tumors) showed 10-year relative survivals of 99% for stage I, 98% for stage II, 96% for stage III, and 77% for stage IV disease (356). The very long natural history makes accurate collection of outcomes and performing clinical trials challenging. Because these tumors are particularly likely to affect young women, decisions regarding fertility-sparing and premature hormonal deprivation are often pertinent.

Early-Stage Borderline Tumors

Surgery

Surgery is the cornerstone of treatment for early-stage borderline ovarian tumors. It is often not known preoperatively whether an ovarian mass will prove to be a borderline tumor, and the accuracy of frozen section in the diagnosis of ovarian tumors has been reported to be low; 20% to 30% of ovarian tumors diagnosed as borderline at the time of frozen section examination proved to be invasive carcinomas on further sampling (357). Issues of surgical management of an ovarian mass

are covered in Section “Surgery.” In general, a systematic, full staging of borderline tumors has been recommended along with salpingo-oophorectomy and omentectomy. This includes biopsies taken from pelvic and abdominal peritoneum, omentum, and retroperitoneal lymph nodes. Appendectomy is recommended as part of staging for MBTs to exclude an appendiceal primary tumor (358). For serous tumors, the prognosis and, in some instances therapy, may depend upon the stage and the presence of invasive implants. However, lymph node involvement in borderline serous tumors has not been shown to affect prognosis, and the role of lymphadenectomy is therefore not clear. In patients undergoing fertility-sparing surgery, a biopsy of a normal contralateral ovary is no longer recommended. In the presence of bilateral adnexal masses, intra-operative decision-making is more difficult if the patient desires fertility-sparing surgery. Removing the more suspicious (excrecences, solid, enlarged) ovary for frozen section analysis and then performing a cystectomy on the contralateral ovary followed by staging biopsies is a reasonable compromise allowing preservation of fertility while providing prognostic information.

Despite the generally accepted recommendation to stage all patients with borderline tumors if detected intra-operatively, the more recent literature shows no substantial clinical benefit to surgical staging of borderline tumors (359). Also there is currently no evidence that prophylactically removing the uterus after completion of childbearing will improve prognosis. Therefore, the role of restaging borderline tumors not fully staged at the time of initial surgery is controversial, and most experts would follow these patients without additional surgery after obtaining a baseline abdominopelvic CT scan and CA-125 (serous) or CEA (mucinous) tumor marker. Some, though not all, series report a higher recurrence rate after incomplete staging, but restaging will have little effect on management in most cases. The relevance of stromal microinvasion, which is found in about 10% of SBT, as an indication for staging is controversial; it is a poor prognostic factor for serous tumors, and is associated with micropapillary histology and peritoneal implants (355). The most relevant situation for restaging appears to be in women with apparent stage I SBT with micropapillary histology, which have the highest risk of invasive implants.

Since many women with borderline tumors are in their childbearing years, the efficacy and safety of conservative surgery are important. There is no evidence that fertility-sparing surgery has an adverse effect on survival in patients with stage I borderline tumors. Even though patients treated with a unilateral oophorectomy have a higher recurrence rate than patients treated with a total hysterectomy and bilateral oophorectomy, effective surgery achieving complete removal of all visible lesions for recurrent disease leads to equivalent survival. At the time of recurrence, most surgeons will perform a hysterectomy and remove the contralateral ovary, especially if a woman has completed childbearing. Whether even more conservative surgery (e.g., cystectomy) has an adverse impact on survival remains a subject of debate. Although cystectomy for a borderline tumor may increase the recurrence rate (up to a 58% recurrence rate has been reported), it may not have an adverse effect on survival, at least for serous tumors. A study reviewing the experience within the Kaiser Permanente medical system found that women treated by cystectomy had a 23% recurrence rate versus 7% in women treated by salpingo-oophorectomy (360). However, in order to avoid recurrences and still maintain fertility, there appears to be little, if any, disadvantage to performing a unilateral oophorectomy. Most patients are able to conceive and deliver after unilateral removal of one ovary. Because of the high risk of death for women with recurrent mucinous tumors, cystectomy for mucinous borderline lesions is not advisable and, in general, every effort should be made to remove mucinous tumors specifically and any other ovarian tumors in general surgically intact. In

patients who present with stage II borderline tumors, a total abdominal hysterectomy and bilateral salpingo-oophorectomy with appropriate staging of the peritoneal cavity is usually recommended.

Prognosis

Early-Stage Serous Borderline Tumors

Approximately 5% to 10% of early-stage SBT have been reported to ultimately recur, although it has been argued (see section “Pathology”) that recurrences of well-staged and sampled stage I tumors are, in fact, very unusual. Recurrences can present very late, 10 to 15 years after the initial diagnosis. In one representative report of 160 stage I SBT, 11 patients developed recurrent tumor at a median of 16 years after initial surgery (range, 7 to 39 years), and 8 died of the disease (361). While the risk of recurrence has been reported to be higher for borderline tumors with micropapillary histology, this may be related to an increased rate of invasive implants; in most series, stage I SBT with micropapillary histology appear to have the same rate of recurrence as stage I SBT without micropapillary patterns. Microinvasion of SBT is discussed in detail in the section “Pathology.” In general, while microinvasion is associated with an increased risk of recurrence, it is also associated with peritoneal implants, and there is no consensus on whether microinvasion is an independent risk factor or whether it, in isolation, warrants restaging surgery (355).

Early-Stage Mucinous Borderline Tumors

MBTs tend to be large, and areas of microinvasion can easily be missed if they are not sampled thoroughly. However, the clinical relevance of this is unclear, as microinvasion does not have clear prognostic significance. A review of 8 series including 116 patients with mucinous ovarian tumors and stromal microinvasion reported that none developed an invasive recurrence. However, median follow-up in a number of these series was under 5 years. In general, while the overall prognosis of early-stage MBTs is excellent, they can occasionally recur, and may recur late. Khoskas and colleagues reported that the rate of recurrence as invasive mucinous tumors after 10 years was 13%. Patients with these recurrences, like those with other advanced-stage mucinous tumors, do poorly.

Systemic Therapy

Chemotherapy is not indicated for stage I or II borderline tumors, regardless of histology or microinvasion.

Advanced-Stage Serous Borderline Tumors

Surgery

Since the role of chemotherapy in the treatment of borderline tumors is unclear, surgery is the primary treatment. Retrospective studies suggest that the proportion of patients achieving optimal cytoreductive surgery is stage-for-stage higher for patients with serous low malignant potential tumors and low-grade serous cancers than for those with serous epithelial ovarian cancer (362). As with higher-grade ovarian tumors, residual disease is an important prognostic factor for both recurrence-free and overall survival. In a series of 168 FIGO stage II and III SBT, 5-year disease-free survival was 75% in patients with no residual disease, 76% in those with residual disease less than or equal to 2 cm, and 56% in those with residual disease greater than 2 cm. No patient with residual disease in this series received adjuvant chemotherapy (363,364).

Prognosis

Residual disease after surgery, the presence of advanced disease prior to surgery, and invasive implants showing clear stromal invasion are poor prognostic factors. Seidman and Kurman reported on a review of 97 publications including 4,129 patients, and noted that after 7.4 years of follow-up, the survival of patients with non-invasive peritoneal implants was 95.3% as compared with 66% for those with invasive implants. Lymph node involvement, as noted above, did not confer a poor prognosis, and was associated with a 98% survival rate at 6.5 years (309). Another report suggested that women diagnosed with invasive implants have 5- and 10-year survival rates of approximately 70% and 40% (365).

It has been suggested that patients with invasive implants recur earlier and those with noninvasive implants recur later. The University of Texas MD Anderson group retrospectively identified 39 patients with ovarian SBT with invasive implants. At a median follow-up of 111 months, 12 (31%) had progressed or recurred with median time from diagnosis to recurrence of only 24 months (366). They also reviewed 80 cases of stage II to IV ovarian SBT with noninvasive implants. Fifty received postoperative chemotherapy. Thirty-five (44%) developed recurrences, 10% within 5 years, 19% between 5 and 10 years, 10% between 10 and 15 years, and 5% more than 15 years after primary resection. Recurrences in patients with noninvasive implants may be either invasive (low-grade serous tumors) or noninvasive. In the series above, 2 of the 35 recurrences were not histologically examined, 6 were recurrent borderline tumors, and 27 were low-grade serous tumors. The patients with recurrent borderline tumors were all alive without evidence of disease 3 to 14 years after the recurrence. Twenty of the 27 patients with low-grade serous carcinomas at the time of recurrence died of disease between 1 and 18 years (median 3 years) after recurrence; the other 7 were alive with progressive disease a median of 4 years after recurrence. Older age was a poor prognostic factor for survival. Shvartzman et al. identified 112 patients with *de novo* low-grade serous carcinomas and 41 with invasive recurrences of borderline tumors. There were no statistically significant differences between the 2 groups in median age (42.7 vs. 45.4 years [at relapse]), progression-free survival (19.5 vs. 25 months), or overall survival (81.8 vs. 82.8 months) (367).

Adjuvant Systemic Therapy

There is no known evidence of benefit of adjuvant systemic therapy for any subset of advanced-stage borderline tumors, although current practice is often to treat patients with invasive implants with chemotherapy similar to that used for ovarian carcinomas (355). Gershenson et al. reported on a representative series of patients with serous borderline ovarian tumors who had macroscopic residual disease after initial surgery, received chemotherapy, and subsequently underwent second-look laparotomy. Three of 20 (15%) patients with noninvasive implants and 4 of 7 (57%) patients with invasive peritoneal implants had a response to chemotherapy (366). Recent data on treatment for low-grade serous carcinomas with chemotherapy are even more discouraging (see treatment for recurrence, below), and the effect of treatment on survival is very uncertain. Shih et al. reported on a retrospective series of 65 patients with stage III/IV disease, of whom 17 received adjuvant chemotherapy. Three-year PFS was 89.9% for patients who did not receive adjuvant chemotherapy, and 70.6% for those who received it. These data were not broken down by type of implant (368). It should be recalled that, as discussed above, not all patients with invasive implants recur, and expert pathological review by a dedicated gynecologic pathologist is recommended if true invasion is suspected. Patients will have a long time to live with any toxicities from chemotherapy and may develop leukemia or other late

side effects. A Cochrane meta-analysis did not find that evidence supported use of any specific type of adjuvant treatment (369).

Therapy for Recurrence

Low-grade serous carcinomas have been reported to be relatively chemotherapy resistant, and surgery remains the mainstay of treatment for recurrent disease. Bristow et al. reported on a series of 26 patients with recurrent low-grade serous carcinoma (370). Twenty-one had received platinum-based chemotherapy after primary surgery. Twenty-one underwent secondary debulking surgery, and 15 were optimally debulked. The median overall survival post recurrence was 56 months, and optimal debulking was the strongest predictor of survival after recurrence. Of 12 patients who received chemotherapy and had measurable disease, 2 had a CR and one had a PR (response rate of 25%). Gershenson et al. reported on a retrospective review of 108 chemotherapy regimens administered to 58 patients with low-grade serous ovarian tumors. There was an overall response rate of 3.7%, with one complete and 3 partial responses. The median time to progression was 29 weeks (312).

Over 90% of serous borderline ovarian tumors are estrogen-receptor positive (371), and there are case reports of major responses to tamoxifen, leuprolide, and anastrozole. The MD Anderson group retrospectively reviewed outcomes of 219 hormonal therapy regimens in 133 women with recurrent low-grade serous carcinomas of the ovary or peritoneum. The overall response rate was 9%, with 6 complete and 2 partial responses (to anastrozole, letrozole, and tamoxifen). Median time to progression was 7.4 months. Time to progression was longer for tumors that were positive for both estrogen and progesterone receptors than for those tumors positive only for estrogen receptors (372).

Bevacizumab has been reported to produce complete responses in 2 women with heavily pretreated recurrent low-grade ovarian tumors (373), and other antiangiogenic agents are of interest in this disease. The Gynecologic Oncology Group has established a separate series of trials for women with low-grade tumors. Since initial reports suggested a high frequency of *KRAS* and *BRAF* mutations in low-grade serous carcinomas, a trial was undertaken with AZD6244 (sulemetenib), which inhibits MEK-1/2 (downstream signaling effectors of *KRAS*/*BRAF* activating mitogenic signaling) in women with low-grade serous carcinomas. The majority had at least 3 prior cytotoxic regimens. Preliminary results suggested a 15% response rate with a median PFS of 11 months. Of patients for whom sufficient tumor material was available, 5% had *BRAF* mutations, 15% had *NRAS* mutations, and 51% had *KRAS* mutations. No correlation between response and mutation status was observed (374,560). Other data also suggest that *BRAF* mutations, while common in early-stage borderline tumors, are rare in advanced-stage low-grade serous carcinomas (375), and therefore agents targeting *BRAF* may not be useful in the treatment of recurrent disease.

MANAGEMENT OF ADVANCED-STAGE DISEASE

A simplified algorithm for the management of presumed advanced-stage ovarian cancer is shown in Figure 24.46. Clinical diagnosis is discussed on page 774.

Surgery

Surgery for advanced-stage disease is covered in the Section “Surgery.” Upfront surgery for definitive diagnosis and removal of as much tumor as possible has long been the standard in ovarian cancer therapy. It is clear that women who are successfully

surgically debulked to minimal or no residual disease have an improved survival, although how much of this is a direct result of the surgical effort and how much reflects unknown biologic/genetic, social, or health factors in patients who have debulking disease, remains unclear. One randomized trial has shown a benefit for “interim debulking” surgery (376). Whether surgery must be performed upfront for optimal benefit, or whether similar outcomes would be achieved with surgery after neoadjuvant chemotherapy, is open to debate.

Postoperative Chemotherapy

Surgery is rarely curative for women with advanced-stage ovarian carcinoma, even when there is no residual disease. As discussed above (see prognostic factors), outcomes are dependent on stage, grade, and histologic subtype. Overall 5-year relative survivals from SEER data are 45% for those with stage IIIa disease and 35% for those with stage IIIc disease (see Fig. 24.43) (292). The most common front-line adjuvant therapy currently used in the United States is 6 cycles of postoperative intravenous paclitaxel/carboplatin administered every 3 weeks. Some physicians administer 8 or 9 cycles of therapy, particularly when interval debulking is performed. However, 3 small, randomized trials that investigated the benefit of prolonging duration of treatment beyond 6 cycles showed an increase in toxicity but no improvement in outcomes (377–379).

Approximately 50% to 70% of patients with measurable disease after surgery will have a complete or partial response to platinum-based first-line postoperative therapy (380,381). In trials including optimally and suboptimally debulked patients, at least half will generally have a complete clinical response to platinum-based regimens, with disappearance of all disease on scan and normalization of CA-125 (382). Unfortunately, even among those with complete clinical remission, the majority eventually develop recurrent disease. In general, primary serous peritoneal cancers, ovarian cancers, and fallopian tube cancers are treated in a similar manner, and are eligible for the same protocols. Areas of controversy or uncertainty include the use of neoadjuvant therapy (discussed above), the use of intraperitoneal chemotherapy, the use of bevacizumab, and the use of dose-dense paclitaxel. Neither addition of other cytotoxic agents nor maintenance therapy after attaining remission has been shown to improve survival.

Platinum Use

Platinum agents are the most active group of chemotherapy drugs in the treatment of ovarian cancer. This may partially be accounted for by the fact that tumors of *BRCA* mutation carriers appear to have particular sensitivity to platinum. The GOG performed a comparative trial of a platinum-containing regimen versus a non-platinum-containing regimen in the pre-taxane era (382). Two hundred twenty-seven patients with advanced ovarian cancer were randomized to receive doxorubicin/cyclophosphamide treatment with or without the addition of cisplatin. Complete response rate (51% vs. 26%) and median overall survival (15.7 vs. 9.7 months) were both superior for the cisplatin-containing regimen. A meta-analysis confirmed that platinum-based therapy produces a survival benefit compared to nonplatinum-based therapy. Subsequently, multiple randomized trials and a meta-analysis have confirmed that carboplatin is as active as cisplatin when both are given intravenously (383), and since carboplatin produces substantially less neurotoxicity, nausea, and ototoxicity, it has become the standard for intravenous use. An early meta-analysis of over 60 published trials showed a correlation between dose intensity of cisplatin and observed response rate, but the correlation held only over a range of doses lower than those used in clinical practice today (384). A large number of trials of varying design have tested higher versus lower

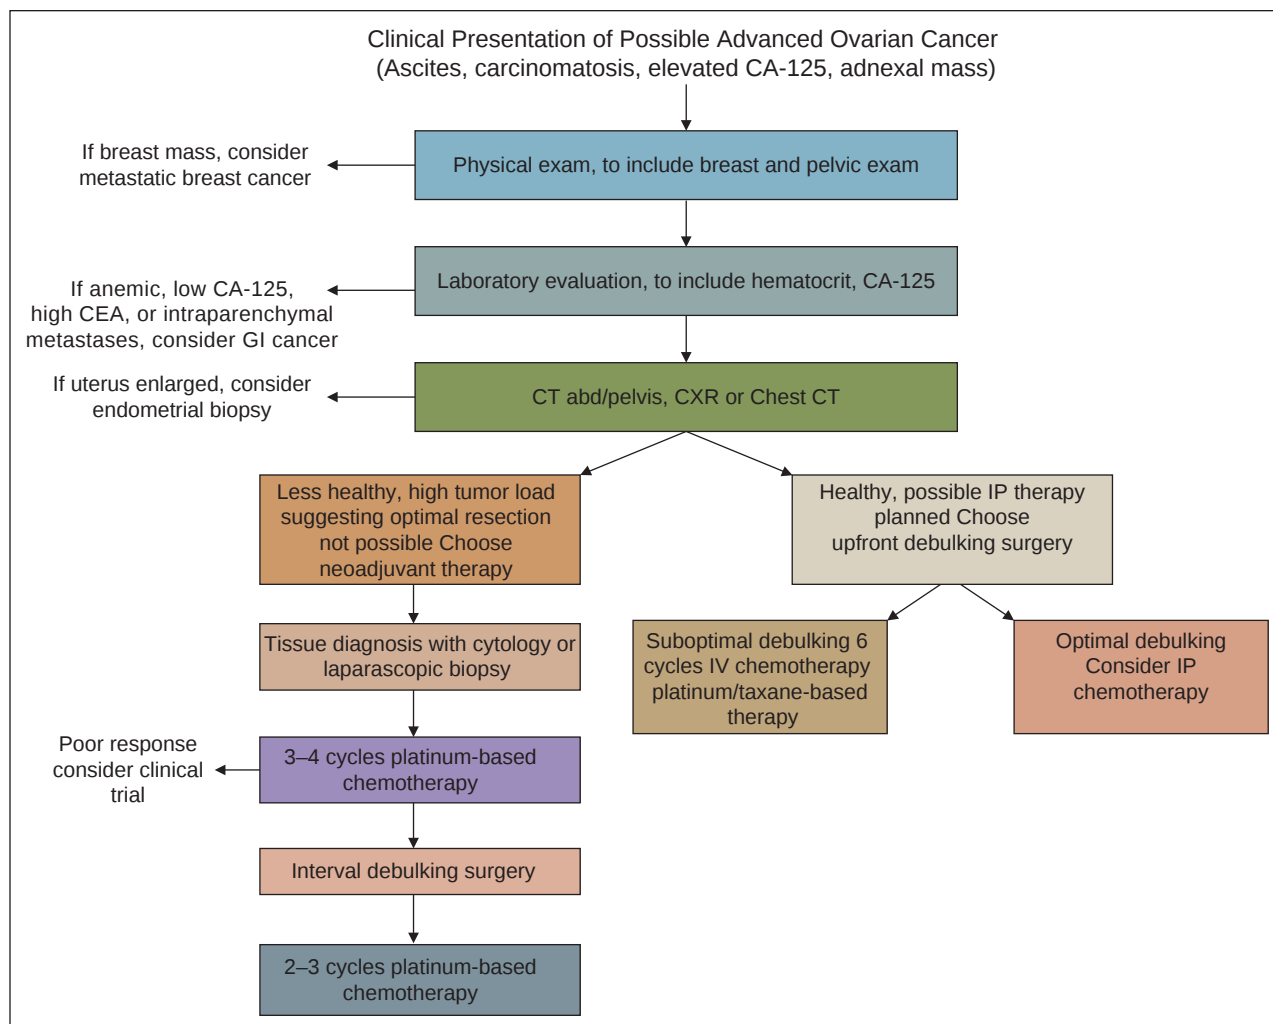

FIGURE 24.46. Simplified Management of Patients Presenting with Probable Advanced Ovarian Cancer

doses of platinum agents, including trials using doses of carboplatin requiring stem cell support, but no good evidence supports the use of doses of cisplatin above 50 mg to 100 mg/m² every 3 weeks or doses of carboplatin over AUC 5 to 7.5 every 3 weeks. AUC 6 is the most common dose used for first-line therapy.

Oxaliplatin, a third-generation platinum agent that produces an unusual cold-triggered neurotoxicity, has a theoretical benefit in activity against tumors that exhibit mismatch repair deficiency, but there is no clinical evidence that it is non-cross-resistant with other platinum agents in general. A GOG trial of oxaliplatin in women with platinum-resistant tumors revealed negligible activity (385). A small ($n = 177$) randomized trial comparing oxaliplatin/cyclophosphamide to cisplatin/cyclophosphamide as first-line therapy in women with ovarian cancer showed no difference in progression-free or overall survival between the 2 treatment groups (386). Oxaliplatin is FDA-approved in the United States for use in colon cancer and, as described below, is being tested as front-line therapy for mucinous ovarian ovarian cancers.

Addition of Paclitaxel to Platinum Chemotherapy

In the 1980s a great deal of excitement was generated by the demonstration that single-agent paclitaxel had substantial activity against platinum-resistant ovarian cancer. A number of

randomized trials were rapidly launched comparing platinum-based regimens with and without taxane in the first-line treatment of ovarian cancer.

The results of the first 2 of these trials (GOG #111 and OV-10) clearly demonstrated that combination chemotherapy with paclitaxel and cisplatin prolonged both progression-free and overall survival as compared with cyclophosphamide/cisplatin (380,387,388). In GOG #111, which included 386 women with suboptimally debulked or stage IV disease, the median overall survival was 37 months for those treated with paclitaxel and cisplatin as compared to 25 months for those receiving cyclophosphamide and cisplatin. Similar results were found in the more inclusive (stages IIB-IV) European OV-10 trial, which reported a median overall survival of 36 months for the paclitaxel containing arm versus 26 months for the cyclophosphamide-containing arm.

The other 2 trials did not as clearly support the addition of paclitaxel to front-line therapy. The 3 arms of GOG #132 were single-agent paclitaxel (200 mg/m² over 24 hours), single-agent cisplatin (100 mg/m²), and the combination of cisplatin 75 mg/m² plus paclitaxel 135 mg/m² over 24 hours (380). Six hundred fourteen women with suboptimally debulked or stage IV disease were treated. The response rate to single-agent paclitaxel in patients with measurable disease was significantly lower than to either of the platinum-containing regimens (42% vs. 67%, $p < 0.01$). However, the difference in median overall survival

(30.2, 25.9, and 26.3 months for patients randomized to cisplatin, paclitaxel, or the combination, respectively) was not statistically significant. The investigators speculated that the lack of benefit for the combination arm related to the fact that almost 50% of patients on the single agent arms began subsequent treatment (frequently with the therapy of the alternate arm, that is, cisplatin for women who were randomized to paclitaxel and paclitaxel for women who were randomized to cisplatin) prior to overt clinical progression, presumably on the basis of a rising CA-125. By way of contrast, paclitaxel was seldom used as salvage therapy in GOG #111 because of its limited availability at the time, and while 48% of patients in the cisplatin/cyclophosphamide arm of OV-10 crossed over to paclitaxel as first salvage treatment, it appears that they did so after overt clinical progression. ICON3, a large ($n = 2,075$) multinational trial which randomized women with stage I–IV disease to carboplatin AUC 6/paclitaxel chemotherapy versus single-agent carboplatin AUC 6 or CAP (cisplatin/doxorubicin/cyclophosphamide) chemotherapy found no superiority for the taxane-containing combination in either progression-free or overall survival (hazard ratio for overall survival 0.98; 95% CI, 0.87 to 1.10) (561). About a third of patients on carboplatin in the control group went on to receive a taxane at some stage, mostly after the disease had progressed. The results of this trial also appear to contradict those of OV-10 and GOG #111, and the explanation remains unclear. However, given that carboplatin plus paclitaxel combination therapy is certainly at least as active as single agent carboplatin, that the combination has been reported to improve survival in a trial for women with recurrent disease (389), and that the doublet is both relatively well tolerated in general and platelet-sparing relative to single agent carboplatin, the combination has become standard.

Alternate Paclitaxel Dosing

The standard dose of paclitaxel in front-line therapy was 135 mg/m² when it was used as a 24 hour infusion and is currently 175 mg/m² as a 3-hour infusion. Neither increasing the dose nor using prolonged infusions is associated with improved outcomes. Paclitaxel was initially administered as a 24-hour infusion to minimize hypersensitivity reactions and to diminish neurotoxicity when it was administered in combination with cisplatin. Since an early randomized phase II trial had suggested slightly better disease-related outcomes with a 24-hour versus a 3-hour paclitaxel infusion, the GOG completed a trial (GOG #162) randomizing women with ovarian cancer to cisplatin 75 mg/m² plus paclitaxel 135 mg/m² with the paclitaxel administered as either a 24- or a 96-hour infusion. There was no difference in overall or progression-free survival (390). Attempts at escalating the paclitaxel dose have also been made. A prospective, randomized trial in previously untreated advanced ovarian cancer patients compared 2 different doses of paclitaxel (175 vs. 225 mg/m²), with all patients receiving carboplatin at an AUC of 5. No improvement in survival was reported for the higher-dose regimen (391).

More recently, based on data in women with metastatic breast cancer that weekly paclitaxel was superior to every 3 week paclitaxel in terms of response and survival, the Japanese Gynecologic Oncology Group randomly assigned 637 women with stages II to IV ovarian cancer, primary peritoneal cancer, or fallopian tube cancer to treatment with standard therapy with carboplatin AUC 6 plus paclitaxel 180 mg/m² over 3 hours every 21 days weeks or dose-dense therapy with carboplatin AUC 6 every 21 days plus paclitaxel 80 mg/m² on days 1, 8, and 15 of a 21 day cycle. The dose dense regimen was superior in terms of both progression-free (28 vs. 17 months; HR 0.71; 95% CI, 0.58–0.88) and 3-year overall survival (72% vs. 65%; HR 0.75 (95% CI, 0.57–0.98)). All subgroups (age, stage, residual disease) appeared to benefit except for women with clear cell or mucinous tumors (392). The advantage of dose dense therapy was maintained at

6.5 years median follow-up; 5-year OS was 59% versus 51%; HR 0.79 (95% CI, 0.63–0.99) (393). Widespread adoption of the regimen has been hindered by concerns about toxicity and desire to see efficacy results confirmed. The dose dense regimen was more myelotoxic than standard therapy, and required an increased number of dose delays and reductions. There has also been concern that patients in Japan might have a different genetic predisposition to myelotoxicity from the weekly regimen than Western populations. Two large confirmatory trials of dose-dense paclitaxel are therefore underway: GOG #262 and ICON 8. GOG #262 randomized women to 6 cycles of either carboplatin AUC 6 plus paclitaxel 175 mg/m² every 3 weeks or carboplatin AUC 6 every 3 weeks plus weekly paclitaxel 80 mg/m². Bevacizumab, given with chemotherapy and then until progression, was optional, but was selected by most patients. This trial has completed accrual, and results should be available soon. ICON 8 is an ongoing 3-arm trial testing standard therapy with carboplatin every 3 weeks plus paclitaxel every 3 weeks, a regimen of carboplatin every 3 weeks plus weekly paclitaxel, and a regimen in which both carboplatin and paclitaxel are given weekly.

Alternate Taxanes

The Scottish Gynaecological Cancer Trials Group tested the incorporation of docetaxel into front-line therapy (394). One thousand seventy-seven women with stage IC to IV ovarian or primary peritoneal carcinoma were randomized to 6 cycles of carboplatin AUC 5 and either docetaxel 75 mg/m² or paclitaxel 175 mg/m². At a median follow-up of 23 months, there was no difference in progression-free (15 months for docetaxel, 14.8 months for paclitaxel) or overall survival (2-year overall survival 64% for docetaxel and 69% for paclitaxel). This was confirmed in a subsequent report with longer follow-up. Docetaxel was associated with less neurotoxicity (11% vs. 30% grade ≥ 2 neurosensory toxicity) and more myelotoxicity (11 patients vs. 3 patients with neutropenic fever). Docetaxel represents an attractive option for patients with or at risk for neurotoxicity.

Albumin-bound paclitaxel has been shown to have activity in ovarian cancer, but has not been compared to paclitaxel. Xyotax, a microparticle-bound paclitaxel, is being tested by the GOG in a randomized trial as consolidation therapy.

Addition of a Third Cytotoxic Agent to Front-Line Chemotherapy

There are no data that addition of any third cytotoxic agent to front-line chemotherapy of ovarian cancer improves outcomes, despite an immense amount of investigation of this strategy. Multiple randomized phase III trials testing the addition of doxorubicin, epirubicin, gemcitabine, and topotecan to a platinum/taxane backbone either sequentially or all at the same time have all been negative. In addition, an international multiarm randomized study was led by the GOG (GOG #182-ICON5) to definitively answer whether triplet cytotoxic chemotherapy improves survival (395). A total of 4,312 advanced-staged ovarian cancer patients were randomized to carboplatin/paclitaxel or carboplatin/paclitaxel combined with either gemcitabine, liposomal doxorubicin, or topotecan. Progression-free survival ranged from 15.4 to 17.5 months across the 4 treatment arms, with an HR of 0.94 to 1.07, which was not statistically different among any of the combination regimens studied.

Substitution of an Alternate Cytotoxic Agent for Paclitaxel

A randomized phase III trial substituting gemcitabine for paclitaxel as front-line therapy showed inferior overall survival for women on the gemcitabine-containing arm (396). Results with

liposomal doxorubicin have been more interesting. The phase III Multicentre Italian Trials in Ovarian Cancer-2 (MITO-2) trial, randomly assigned 820 chemotherapy-naïve patients with stage IC to IV ovarian cancer to carboplatin AUC 5 plus paclitaxel 175 mg/m² or to carboplatin AUC 5 plus PLD 30 mg/m², every 3 weeks for 6 cycles. The primary end point was progression-free survival (PFS). Median PFS was 19.0 and 16.8 months with carboplatin/PLD and carboplatin/paclitaxel, respectively (HR, 0.95; 95% CI, 0.81 to 1.13; $p = 0.58$). Median overall survival times were 61.6 and 53.2 months with carboplatin/PLD and carboplatin/paclitaxel, respectively (HR, 0.89; 95% CI, 0.72 to 1.12; $p = 0.32$). Carboplatin/PLD produced less neurotoxicity and alopecia but more hematologic adverse effects. There was no relevant difference in global quality of life after 3 and 6 cycles (397). This regimen has not been widely adopted for front-line therapy, in part because the usual dose of carboplatin in the United States is AUC 6, and there are concerns about hematologic toxicity if this dose were added to PLD, partly because of new data about possible superiority of weekly paclitaxel (393), and partly because paclitaxel has been relatively easy to combine with other nonneurotoxic agents, and PLD can be more problematic in this regard. There was, moreover, a shortage of PLD in 2012. Nonetheless, the regimen appears at least as effective as standard dose paclitaxel/carboplatin, and may be an option for patients with severe neuropathy or taxane allergies.

Addition of Bevacizumab to Primary Chemotherapy

Bevacizumab is a humanized monoclonal antibody targeting vascular endothelial growth factor (VEGF). Elevated vascular endothelial growth factor (VEGF or VEGF-A) expression occurs in all stages of ovarian cancer and is associated with poor prognosis, including shorter survival. Bevacizumab as a single agent has produced response rates in the range of 15% to 20% in the setting of recurrent ovarian cancer (398,399,400), which are higher than the response rates seen for other solid tumors. There was therefore great enthusiasm for the addition of bevacizumab to up-front chemotherapy, and 2 large randomized trials have been performed in this setting, both showing an improvement in progression-free survival, but no improvement in overall survival (Table 24.14).

GOG #218 was a placebo-controlled 3-arm study in women with stage III (incompletely resectable) and stage IV disease (401). This trial compared a control group receiving carboplatin AUC 6/paclitaxel 175 mg/m² to carboplatin/paclitaxel with concomitant bevacizumab (15 mg/kg every 3 weeks) and to carboplatin/paclitaxel with concomitant bevacizumab followed by maintenance

bevacizumab for an additional 16 doses (once every 3 weeks). In groups receiving bevacizumab, it was not started until cycle 2, to avoid postoperative wound healing problems. Median PFS for the 3 arms was 10.3 months, 11.2 months, and 14.1 months, respectively, but there were no significant differences in overall survival between the groups. The experimental regimen was tolerable; bowel perforation or fistula requiring medical intervention occurred in 1.2% of patients in the control arm, 2.8% of patients in the concomitant-only bevacizumab arm, and 2.6% of patients in the concomitant plus maintenance bevacizumab arm. As the primary endpoint of the study was progression-free survival, the blind was not maintained after progression, and the authors noted that the endpoint of overall survival could be contaminated by effect of postprogression therapy.

A second trial, ICON7, was led by European investigators (381). This study had only 2 arms: carboplatin/paclitaxel and carboplatin/paclitaxel with concomitant and 12 additional cycles of consolidation bevacizumab). There was no placebo, the bevacizumab dose used was 7.5 mg/kg every 3 weeks rather than the 15 mg/kg used in the GOG #218 trial, and women with both high-risk early-stage and with more advanced disease were eligible to participate. The median PFS for the control group was 17.3 months versus 19 months for the group receiving bevacizumab. Overall survival was not mature at the time of publication. The hazard ratio for death in the bevacizumab group was 0.85 (0.69–1.04). The most important increase in toxicity was a risk of grade 2 or higher hypertension (18% with bevacizumab and 2% with standard therapy) and the risk for grade 3 or higher thromboembolic events (7% with bevacizumab vs. 3% with standard therapy). A separate analysis was conducted in the 30% of participants considered “at high risk for progression,” that is, stage IV or stage III with more than 1.0 cm residual disease after debulking surgery, and this showed a median PFS/overall survival of 10.5 months/28.8 months for the control arm versus 15.9 months/36.6 months for the bevacizumab-containing arm (Fig. 24.47).

Based on the results of GOG 218 and ICON7, the European Medicines Agency approved the use of bevacizumab in combination with paclitaxel plus carboplatin for the front-line treatment of advanced ovarian cancer in the European Union. Bevacizumab is not FDA-approved in the United States for any use in ovarian cancer at the time of this writing. Issues discussed have included uncertainty about the appropriate duration of bevacizumab therapy, the lack of overall survival benefit seen with bevacizumab in either study as a whole, lack of any molecular predictors for benefit in a specific patient, and the cost of the drug. Since the progression-free survival curves for both GOG #218 and ICON 7, which administered bevacizumab only for a fixed period of time after completion of chemotherapy,

Table 24.14 Randomized Trials ± Bevacizumab

appeared to converge at some point after discontinuation of bevacizumab (nonproportional hazards), it has been hypothesized that the bevacizumab benefit is dependent on continued administration. In addition, there is concern about the lack of overall survival benefit seen in the 2 studies as a whole, and while this might be the result of crossover to receive bevacizumab after progression in the U.S. GOG #218 trial, this is less likely to have been the case for the largely European ICON 7 trial. If the overall benefit of bevacizumab can be realized by administration in the second-line setting (see treatment of recurrent disease, below), fewer women might need to be exposed to the agent for similar benefit.

Intraperitoneal Chemotherapy

Intraperitoneal (IP) chemotherapy is a form of dose-escalation; it provides a means by which high concentrations of drugs and long durations of tissue exposure can be attained at the peritoneal surface. Since intraperitoneal progression of disease remains the major source of morbidity and mortality in ovarian cancer, it is a theoretically attractive approach in the treatment of this disease. Many chemotherapeutic agents, including those used for the treatment of ovarian cancer such as cisplatin,

carboplatin, topotecan, and paclitaxel have been tested for feasibility with intraperitoneal administration. Larger or less water-soluble molecules will stay longer in the peritoneal cavity, and have a higher peritoneal cavity-to-plasma concentration ratio (sometimes referred to as “pharmacologic advantage”), but may not get into the bloodstream. The direct penetration of chemotherapy agents into tumor masses is limited to 1 to 2 mm from the tumor surface. Early work by Los et al., using a rat intraperitoneal tumor model, found that the concentration of cisplatin at the periphery of tumor nodules was higher after IP administration of cisplatin, but the concentration at the center of the nodules was identical after IP and intravenous administration (402). Hence (a) the theoretical benefit is only for very small tumor volumes, and (b) agents that do not reach therapeutic systemic levels when given by the intraperitoneal route need to be administered intravenously as well. Cisplatin has a 10- to 20-fold pharmacologic advantage when given intraperitoneally. For a given dose of cisplatin, peak concentrations are higher with intravenous cisplatin, and this has resulted in somewhat decreased toxicity in a randomized comparison of the same doses of cisplatin given intraperitoneally versus intravenously, including less hearing loss and neuromuscular toxicity (403). However, the amount of cisplatin recovered in the urine, reflecting total systemic exposure, is similar regardless of whether the

administration is intravenous or intraperitoneal. Similarly, carboplatin given IP at an AUC of 6 has been shown to produce an AUC in the peritoneal cavity about 17 times higher than that of carboplatin given intravenously while producing a very similar serum AUC (404). Paclitaxel, on the other hand, has a pharmacologic advantage of about 1,000, and significant levels persist in the peritoneal cavity 1 week after drug administration. However, the dose that can be given is limited by abdominal pain, and serum paclitaxel concentrations detected in patients treated with intraperitoneal paclitaxel at feasible doses are low (405).

Clinical Use of Intraperitoneal Therapy for Ovarian Cancer

In January 2006, the NCI issued a clinical alert supporting the use of intraperitoneal cisplatin chemotherapy in women with optimally surgically debulked ovarian cancer (406). A meta-analysis of 8 trials comparing intraperitoneal to intravenous platinum-based chemotherapy (all but one used cisplatin) showed an average 21.6% decrease in the risk of death (hazard ratio 0.79; 95% CI, 0.70 to 0.89). Since the expected median duration of survival for women with optimally debulked ovarian cancer receiving standard treatment is approximately 4 years, this size reduction in the death rate was estimated to translate into about a 12-month increase in overall median survival. The power of this analysis was based primarily on the survival benefits for intraperitoneal chemotherapy observed in each of the 3 relatively large randomized trials summarized in Table 24.15 (403,407,408).

Despite these results, intraperitoneal therapy has not yet been consistently adopted for the treatment of women with optimally debulked ovarian cancer in the United States, and has not been widely adopted internationally. There are several reasons for this.

First, intraperitoneal therapy, as used in the reported trials, is technically demanding. Administration of paclitaxel over 24 hours, which is necessary to reduce the neurotoxicity when

paclitaxel is combined with cisplatin, is inconvenient and, if it requires hospitalization, expensive. Use of IP catheters is not routine in many oncology practices, and is associated with a number of complications. A recent review of published reports (409) noted that complications involving fully implantable peritoneal catheters used for peritoneal access occurred at overall rates of 6.8% to 40.5% and were responsible for the failure to complete planned IP chemotherapy in 1.9% to 26.2% (mean 12.6%) of patients. Obstruction (37.6%) and infection (31.4%) were the most common complications. Other issues included leakage, retraction of the catheter, rotation of the portal, difficulties with access, and perforation of the bowel. There are no proven methods to minimize these complications. Although infection may theoretically be reduced by the avoidance of placement during grossly contaminated surgeries, there are no hard data on the influence of associated bowel surgery at the time of intraperitoneal catheter placement. There is no proven way to prevent the adhesions that cause catheter obstruction. The review did not find any difference in the rates of complications between fenestrated or unfenestrated ports.

Second, all of the large randomized studies used cisplatin in both the intraperitoneal and intravenous arms, whereas carboplatin, which is less toxic and easier to administer, has become the standard intravenous platinum agent in the treatment of ovarian cancer. Although intraperitoneal carboplatin can be safely used and appears to have favorable pharmacokinetics (pharmacologic advantage combined with good systemic drug exposure), there is not yet evidence that it will provide the same survival benefits as intraperitoneal cisplatin.

Finally, the heterogeneity and toxicity of the intraperitoneal regimens used have left some confusion as to the most important elements of intraperitoneal therapy. For example, the trial reported by Markman et al. used 2 cycles of carboplatin AUC 9 (as “chemical debulking” prior to starting intraperitoneal therapy), which resulted in significant hematologic toxicity and difficulty delivering the IP regimen (408). The Armstrong trial (GOG #172) incorporated both intraperitoneal cisplatin and intraperitoneal paclitaxel. Intravenous paclitaxel was given day

Table 24.15 Selected Randomized Trials of Intraperitoneal Versus Intravenous Chemotherapy in Optimally Debulked Ovarian Cancer

Author (yr)	N	Regimens	Median PFS	Median OS	Comments
Alberts (1996) ⁴⁰³	546	IV cyclophosphamide 600 mg/m ² plus IP cisplatin 100 mg/m ² × 6 vs. IV cyclophosphamide 600 mg/m ² plus IV cisplatin 100 mg/m ² × 6	N/A	49 mo vs. 41 mo <i>p</i> = 0.02	<2 cm residual disease permitted; 58% of patients in both groups completed 6 cycles of cisplatin
Markman (2001) ⁴⁰⁸	462	IV carboplatin AUC 9 × 2 followed by IV paclitaxel 135 mg/m ² /24 h plus IP cisplatin 100 mg/m ² × 6 vs. IV paclitaxel 135 mg/m ² /24 h plus IV cisplatin 75 mg/m ² × 6	28 mo vs. 22 mo <i>p</i> = 0.01	63 mo vs. 52 mo <i>p</i> = 0.05	18% of patients on IP arm got ≤2 cycles of IP therapy
Armstrong (2006) ¹⁸³	416	D1 IV paclitaxel 135 mg/m ² /24 h D2 IP cisplatin 100 mg/m ² D8 IP paclitaxel 60 mg/m ² vs. D1 IV paclitaxel 135 mg/m ² /24 h	24 mo vs. 19 mo	67 mo vs. 50 mo	49% of patients received ≤3 cycles of IP therapy

Note: IV, intravenous; IP, intraperitoneal; OS, overall survival; PFS, progression-free survival; mo, months.

1 and intraperitoneal paclitaxel day 8, leading to speculation that the benefit of the regimen was related to the day 1,8 schedule of paclitaxel administration (“dose-dense”) rather than the intraperitoneal route of chemotherapy administration.

Despite these uncertainties, a potential 1-year survival advantage is certainly meaningful. In GOG #172, the survival benefit was seen even though only 42% of patients on the IP arm received the 6 planned cycles of intraperitoneal therapy due either to cisplatin-related toxicities or catheter problems. The option of intraperitoneal therapy should be discussed with all healthy patients who have optimally debulked ovarian cancer.

Ongoing Trials with Intraperitoneal Therapy

Ongoing trials, including GOG #252, JGOG-3019, and OV-21, are addressing some of the issues regarding optimization of IP chemotherapy regimens. GOG #252 has 3 arms: the carboplatin plus dose-dense paclitaxel (all intravenous) regimen published by the JGOG, the same regimen with the carboplatin administered intraperitoneally instead of intravenously, and a third arm which is a modification of the regimen used in GOG #172 and prescribes paclitaxel 135 mg/m² intravenously over 3 hours day 1, cisplatin 75 mg/m² IP on day 2 and paclitaxel 60 mg/m² IP on day 8. All 3 arms are combined with bevacizumab, which is administered every 3 weeks and continued for 22 cycles. GOG #252 has completed accrual, and results are pending. In the iPocc trial (GOTIC-001/JGOG-3019), dose-dense weekly paclitaxel at 80 mg/m² intravenously is administered in combination with either IV or IP carboplatin AUC 6 every 3 weeks. Patients with stages II to IV disease are eligible; hence this study will explore the potential of IP chemotherapy in suboptimally debulked disease. It is certainly possible that intraperitoneal therapy might benefit women other than those with initially optimally debulked cancer. For example, some patients might be “chemically debulked” by their first few cycles of chemotherapy. The Alberts trial (Table 24.15), perhaps the cleanest test of intraperitoneal therapy in that all variables were the same in both arms except the route of cisplatin administration, permitted accrual of women with up to 2 cm of residual disease. Benefit of therapy was not influenced by extent of residual disease ($p = 0.93$ for interaction of treatment and residual disease, microscopic vs. ≤ 0.5 cm vs. >0.5 to 2 cm). The third ongoing randomized trial of IP therapy is the OV-21/GCIG study lead by the Canadian National Cancer Institute, and incorporates intraperitoneal therapy after neoadjuvant treatment. Patients with stage III disease receive neoadjuvant chemotherapy. Those who respond will receive interval debulking surgery, and if the residual disease after interval debulking surgery is less than 1 cm, they are randomized to one of the 3 arms. The control arm is the combination of intravenous paclitaxel at 135 mg/m² followed by intravenous carboplatin AUC 5 on day 1, and then intravenous paclitaxel at 60 mg/m² on day 8. The second arm is same as the control arm except that carboplatin and day 8 paclitaxel are given by the IP route. The third arm is the same as the second arm, except that intraperitoneal cisplatin 75 mg/m² is substituted for intraperitoneal carboplatin. One of these 2 IP arms (arm 2 or arm 3) will be chosen as a randomized phase II winner, and will then be compared to the control arm in a phase III manner.

Consolidation/Maintenance

Many women with ovarian cancer have an excellent response to first-line chemotherapy, but most will nonetheless relapse and die of their disease. Approximately two-thirds of patients with advanced ovarian cancer will achieve a clinical complete remission following chemotherapy, that is, have no evidence of disease on physical examination or in radiographic studies together with a serum CA-125 in the normal range. In the days

when second-look laparotomy was used, about one-third of all patients with advanced ovarian cancer were free of disease at a second-look laparotomy following primary cisplatin-based therapy. Such operations, whose purpose was prognostic, are no longer generally performed, because no therapy instituted as a result of disease found at second-look surgery was found to alter prognosis, and over half of those patients who initially presented with stage III or IV disease will recur after a negative second-look operation.

Further therapy after a clinical complete remission would clearly be warranted for many women if an effective treatment could be found. However, despite extensive investigation, no trials of consolidation or maintenance therapy have produced any survival benefit to date. The most promising strategies tested have been maintenance paclitaxel and maintenance bevacizumab, both of which appear to delay progression without improving overall survival.

Consolidation with Intraperitoneal Chemotherapy

The EORTC randomized women with a pathologic complete remission to front-line platinum-based therapy to no further therapy versus 4 cycles of intraperitoneal cisplatin at 100 mg/m². The trial closed early with less than half of its planned accrual. After a median follow-up of 8 years, the hazard rates for progression-free survival (PFS) and overall survival (OS) were 0.89 (95% CI, 0.59 to 1.33) and 0.82 (95% CI, 0.52 to 1.29). These results were felt to be suggestive of a treatment benefit but insufficient to change practice (410).

Consolidative Radiotherapy

A randomized trial conducted by the GOG of intraperitoneal ³²P versus observation after pathologic complete response to primary therapy was negative (340). Whole abdominal radiotherapy after chemotherapy is problematic because of complications including myelosuppression, radiation enteritis and bowel obstruction. Using conventional techniques, WAR is not able to deliver adequate radiation doses to the upper abdomen, due to limiting toxicities to organs such as liver and kidneys. Several very small randomized trials have been conducted with contradictory results. Nonetheless, some of the results have been intriguing. For example, the Swedish-Norwegian Ovarian Cancer Study Group randomly assigned 98 patients with stage III ovarian cancer who had a pathologic complete response (CR) at second-look surgery after 4 courses of cisplatin/anthracycline chemotherapy to no further therapy, continued chemotherapy with cisplatin/anthracycline to ten courses total, or whole abdominal radiotherapy. Progression-free survival was significantly better (5-year PFS, WAR = 56%, chemotherapy = 36%, control = 35%, $p = 0.032$) and overall survival trended toward better in the group receiving WAR (411). As discussed above in Section “Early-Stage Disease,” there may be a role for radiation in early-stage clear cell carcinomas, and in this situation pelvic radiotherapy might be able to produce the same benefit as whole abdominal radiotherapy.

Consolidative/Maintenance Chemotherapy

As is the case for use of a third cytotoxic agent in front-line combination therapy, use of a third cytotoxic agent for consolidation/maintenance therapy has not proven effective to date. Two large trials of 4 cycles of consolidative topotecan after primary chemotherapy have both been negative, although they did not require a complete response after primary chemotherapy for eligibility (412,413). Consolidation therapy with epirubicin also failed to improve survival in patients who achieved a clinical complete

remission following platinum-based induction therapy (414). Two small prospective trials of high-dose consolidation therapy with hematopoietic stem cell support have both been negative (415,416).

Paclitaxel Maintenance Therapy

The most promising trial of maintenance therapy to date has been a Southwest Oncology Group (SWOG)/GOG trial randomizing women in clinical complete remission to either 3 or 12 cycles of intravenous paclitaxel 175 mg/m² every 4 weeks (417). The trial was halted by its data and safety monitoring board after a planned interim efficacy analysis at a point when there was a statistically significant improvement in time to progression but no difference in overall survival between the treatment arms (PFS 28 vs. 21 months, one sided $p = 0.0035$). Because insufficient patients to detect a survival difference had been randomized at the time the study was stopped ($n = 262$), and because patients receiving 3 cycles of therapy were allowed the option of crossing over to 12 cycles, a survival comparison was not possible. The neurotoxicity observed was substantial, even though patients with higher than grade 1 neurotoxicity were excluded from the trial, and the dose of paclitaxel was decreased during the study conduct to 135 mg/m² every 4 weeks. However, not very many patients had accrued to the lower dose at the time of study closure, and they were not included in the analysis, so the effect of this dose reduction on therapy efficacy is uncertain. An unplanned retrospective subgroup analysis suggested a trend toward survival benefit in the group of patients who started maintenance therapy with a CA-125 level of less than ten (418).

A subsequent Italian study group randomized 200 patients with stages IIb to IV disease who were in clinical or pathologic complete response after 6 courses of paclitaxel/platinum-based chemotherapy to either observation or 6 consolidation courses of paclitaxel 175 mg/m² every 3 weeks. Grade 2 or greater sensory neurotoxicity was reported in 28.0% of the paclitaxel-arm patients. Two-year progression-free survival rates were 54% and 59% ($p =$ not significant) in the control and maintenance arms, respectively. Corresponding 2-year overall survival rates were 90% and 87% ($p =$ not significant) (419). The GOG is currently conducting a larger trial, GOG #212, randomizing women after clinical complete remission after primary therapy for stage III or IV disease to one of 3 arms: no further therapy, paclitaxel 135 mg/m² every 4 weeks for 12 cycles, or Xyotax (CT-2103, a microparticle-bound paclitaxel) 135 mg/m² every 4 weeks for 12 cycles. This trial has overall survival as the endpoint.

Maintenance with Noncytotoxic Agents

Noncytotoxic agents such as interferon (420), a monoclonal antibody targeting CA-125 (oregovomab) (421), radioimmunoconjugates including intraperitoneal administration of a 90Y-conjugated antimucin antibody (422), and matrix metalloproteinase inhibitors have all been tested in phase III trials with no improvement in survival. The EORTC recently reported that the use of the epithelial growth factor receptor (EGFR) tyrosine kinase inhibitor, erlotinib, for 2 years after nonprogression on front-line therapy provided no benefit (423). The use of bevacizumab is discussed above. Since the GOG #218 trial showed no benefit in terms of progression-free survival when bevacizumab was given concomitantly with chemotherapy but not as maintenance thereafter, it seems probable that the benefit is derived from the maintenance administration of the agent. However, as discussed, no overall survival benefit was seen even with concomitant and maintenance administration of bevacizumab. Numerous trials of other antiangiogenic agents in the consolidation/maintenance setting are ongoing.

SPECIFICS OF EPITHELIAL OVARIAN CANCER WITH CLEAR CELL AND MUCINOUS HISTOLOGY, INCLUDING ADVANCED DISEASE

Until recently, clinical trials for epithelial ovarian cancer included all histologic subtypes together. However, it is becoming increasingly obvious that this is not appropriate, and that the different histotypes are both biologically and clinically distinct, a fact supported by both clinical observation and molecular profiling (424). Because high-grade serous tumors make up about two-thirds of advanced-stage disease (see Table 24.12) there has generally been little power to draw conclusions about the relative benefit of the treatment under study to less common subtypes. However it has become obvious that advanced-stage clear cell and mucinous tumors have a worse prognosis than advanced-stage serous tumors, which may be related to lower sensitivity to standard cytotoxic chemotherapy. A review of all patients entered into advanced-stage GOG ovarian cancer trials from 1976 to 1982, when response was commonly surgically assessed, revealed no negative second-look laparotomies among women with clear cell or mucinous histology (425).

Clear cell Carcinomas

Clear cell carcinoma accounts for 1% to 12% of epithelial ovarian carcinomas in the United States, but 15% to 25% of epithelial ovarian cancers in Japan. Asian women in the United States who get ovarian cancer are twice as likely to have a clear cell cancer as White women. In Japan, as in Western countries, clear cell carcinoma tends to present at an early-stage; in one review, 39% of clear cell cancers were stage I, 13% stage II, 30% stage III, and 6% stage IV (426). Histologic diagnosis may be challenging (see Section “Pathology”), since some high-grade serous carcinomas have a clear cell component, and may be misclassified as clear cell carcinomas. A high-frequency of capsular rupture during surgery for clear cell carcinoma has been reported. In the EORTC-ACTION trial, capsule rupture was reported in 44% of clear cell carcinomas versus 19% of serous tumors. The vast majority were due to intraoperative rupture. A recent review of early-stage clear cell ovarian cancer in British Columbia found that 5-year disease survival for all patients with FIGO stage IC clear cell disease was 67% versus 84% for those stage IA/B clear cell tumors. Patients with capsular rupture alone, with no positive cytology or surface involvement, had a prognosis similar to those with stage IA disease (339).

Molecular studies suggest a distinct profile for clear cell carcinomas. Unlike high-grade serous tumors, they are generally p53 wild-type, and they have a lower frequency of *BRCA 1* and 2 germline mutations than high-grade serous tumors. They have low levels of chromosomal instability and a high frequency (up to 40%) of phosphoinositide 3-kinase catalytic alpha (PIK3CA) mutations. *ARID1A*, a tumor suppressor gene, appears to be mutated in almost half of clear cell carcinomas (36). Gene expression profiling suggests similarities between clear cell carcinomas of the ovary, endometrium, and kidney. For example, the VHL target, HIF1A, appears to be expressed at a higher level in ovarian clear cell carcinoma compared to other histologic types (427). However the somatic and germline mutations of the VHL gene observed in renal clear cell carcinoma have not been observed in ovarian clear cell tumors (351).

As discussed above (Section “Early-Stage Disease”), the implications of clear cell histology in early-disease are not clear; in some reports it seems to portend a high-risk of recurrence, and in others it appears to have little prognostic significance. The benefits of adjuvant chemotherapy are uncertain, and some reviews have suggested little benefit (428). A subgroup analysis

of the EORTC-ACTION trial also suggested that clear cell carcinomas did not appear to benefit from chemotherapy, but the numbers were small. Five-year disease-free survival in the 37 patients on the observational arm was 71%, while it was 60% in patients treated with chemotherapy. It has been suggested that radiation therapy might improve survival in women with stage IC/II disease (339).

Regardless, it has become increasingly clear that advanced-stage clear cell carcinomas do not respond as well to platinum-based chemotherapy as do high-grade serous tumors, possibly because of their lower proliferation rate. As early as 1996, Goff et al. reported that 52% of stage III clear cell tumors of the ovary versus 29% of serous tumors progressed clinically during the course of primary platinum chemotherapy (429). Reported response rates for women with clear cell carcinomas in front-line trials range from 22–56% versus over 70% for women with serous carcinomas (351), variability that may be due, in part, to misclassification of high-grade serous tumors with clear cells as clear cell carcinomas (see section “Pathology”). Survival is also poorer. In 2010 a meta-analysis which included data from over 8,000 patients on 7 international front-line trials using platinum-based regimens identified 221 women with stage III/IV clear cell carcinoma. These women had a median overall survival of 21.3 months versus 40.8 months for women with serous carcinomas (430).

Even worse results have been reported in the setting of recurrent disease, and it does not seem to matter whether the disease is platinum-sensitive or platinum-resistant by traditional definitions. Investigators from M. D. Anderson published a retrospective review of 51 patients treated at their institution for recurrent clear cell carcinoma. Among those with platinum-sensitive disease, only 2 (9%) of 22 patients had a partial response to retreatment with carboplatin and paclitaxel; none of 29 patients given second-line therapy for platinum-resistant disease responded (431). In another study of 75 Japanese women with at least 2 lines of prior systemic therapy, those whose tumors recurred greater than 6 months after completion of chemotherapy had a response rate of 8% versus a response rate of 6% for those whose tumors progressed within 6 months of completing primary chemotherapy (351). This may be because most recurrences occur in women who presented with completely resected stage I disease, and hence there was no way of knowing if the tumor actually shrank in response to chemotherapy, making “platinum sensitive” a misnomer.

There are few data suggesting what treatments might be effective for clear cell carcinomas. Based on some reports that irinotecan plus cisplatin had activity in some patients with clear cell carcinoma, a randomized phase II front-line study was performed by the Japanese Gynecologic Oncology Group (JGOG). Women were randomized to therapy with either carboplatin/paclitaxel or cisplatin/irinotecan (432). Among patients with measurable disease the response rate was 25% (2 of 8) in the irinotecan/cisplatin arm and 40% (2 of 5) in the carboplatin/paclitaxel group. Among women with no residual disease over 2 cm, PFS tended to be longer in the cisplatin/irinotecan group, though the difference was not statistically significant. A multinational phase 3 study for stage I to IV clear cell carcinoma of the ovary using the same 2 regimens has been completed, and results are awaited.

There has also been interest in the use of mTOR inhibitors, because they have activity in patients with advanced renal cell carcinoma, and because PIK3CA mutations have been reported to be common in clear cell carcinomas of the ovary. A report of use of weekly temsirolimus in 5 evaluable patients with heavily pretreated clear cell carcinoma of the ovary noted one partial response of 14 months duration (433). The GOG has launched a frontline single-arm phase II trial (GOG #268) testing the combination of carboplatin, paclitaxel, and temsirolimus followed by consolidation temsirolimus in the treatment of stage III/IV clear cell carcinoma of the ovary. Antiangiogenic agents, which likewise have activity in the treatment of renal cell carcinoma,

may also be useful. There is anecdotal evidence of the activity of sunitinib in clear cell carcinoma of the ovary, and the GOG is performing a trial, GOG #254, of sunitinib in the treatment of persistent or recurrent clear cell carcinoma. One report described one partial response and 2 patients with stable disease among 5 women with ovarian clear cell carcinoma who were treated with gemcitabine (434).

Interestingly, multiple reports suggest that women with clear cell carcinomas are more likely to have a thromboembolic event. Goff et al. noted that 42% of patients with stage III clear cell tumor had deep venous thrombosis (DVT) or pulmonary embolus (PE) versus 18% of patients with serous tumors (429); another more recent retrospective study reported that 42% of patients with clear cell carcinoma had a venous thromboembolic event versus only 22% of patients with other histologies. Half of the events occurred postoperatively (435). Hypercalcemia related to paraneoplastic expression of parathyroid hormone-related peptide has also been reported to be more common in clear cell carcinoma of the ovary than in other subtypes (436).

Mucinous Tumors

When gene expression arrays are performed, mucinous tumors group separately from serous, endometrioid and clear cell ovarian carcinomas. They often more often have *K-RAS* mutations. Unlike colorectal adenocarcinomas, they are often immunoreactive for CK7; unlike other ovarian cancers they are frequently immunoreactive for CK20 and CDX2 (which are usually diffusely and strongly reactive in colorectal adenocarcinomas), though the staining is often weak and focal (437). Early-stage mucinous tumors tend to be low-grade and have a good prognosis. They are unlikely to have metastasized to lymph nodes, and as discussed above (see Section “Early-Stage Disease”), lymph node dissection may not be needed in stage IA mucinous tumors. Advanced-stage mucinous tumors, which are uncommon, respond poorly to chemotherapy and are associated with a short survival for both stage III and stage IV disease (300,438). The overview cited above by MacKay et al. found the median disease free survival for women with stage III/IV mucinous tumors to be only 14.6 months, even shorter than that for women with clear cell disease. It is now known that many tumors thought initially to be advanced-stage mucinous tumors in older studies actually represent metastatic disease from another site, so it is difficult to interpret published results. In a recent international front-line trial for stage III/IV disease that tested 5 different regimens of cytotoxic chemotherapy in 4000 women, 44 cases were classified as mucinous adenocarcinoma. Only about one-third of these judged to be primary mucinous carcinomas by the 3 central reviewers; the remainder were thought to represent metastatic disease from another site. The median survival did not differ significantly between the groups considered primary or metastatic, but survival for both groups was significantly shorter than the survival for women with serous carcinoma (14 versus 42 months, $p < 0.001$) (439).

Based on similarities of mucinous ovarian cancers to colorectal carcinomas, a currently active international trial, GOG #241, is comparing carboplatin/paclitaxel with or without bevacizumab to capecitabine/oxaliplatin with or without bevacizumab.

CARCINOSARCOMA

Ovarian carcinosarcomas tend to present with advanced disease, and early-stage tumors are unusual. Stage III ovarian carcinosarcoma is more common than either stage III mucinous ovarian cancer or stage III clear cell cancer (Table 24.11). Ovarian

carcinosarcoma occurs at a slightly older age and has a worse prognosis overall than epithelial ovarian cancer without sarcomatous differentiation (440), with a median overall survival in the range of 9 to 24 months (441). One small series reported a median overall survival of 62 months for 9 patients with stage I/II disease (442). In recent reports the presence of homologous versus heterologous elements has not been found to have any clear influence on outcomes. The presence of more than 25% sarcomatous histology has been linked to a worse prognosis. Although prospective data regarding the value of debulking surgery do not exist, optimal cytoreduction is associated with improved outcomes, and it is recommended that operative management of these tumors resemble that of epithelial ovarian cancer. Adjuvant chemotherapy is also generally recommended, although randomized trials showing benefit do not exist. Prospective GOG trials reported response rates of 10% for single agent doxorubicin, 18% for ifosfamide, and 20% for cisplatin. Retrospective series have suggested that platinum-containing regimens produce higher response rates than non-platinum-containing regimens, but the optimal regimen remains unknown, and it is unknown whether the percentage of sarcomatous histology in the tumor should influence choice of regimen. One series suggested improved outcomes with cisplatin/ifosfamide versus carboplatin/paclitaxel; another suggested superior outcomes with carboplatin/paclitaxel versus other regimens (440). Ifosfamide-containing regimens are generally more toxic. A case-control series of 50 cases of carcinosarcoma of the ovary treated with first-line platinum-taxane based therapy and 100 cases of papillary serous ovarian cancer matched by age, stage, and year of diagnosis showed response rates to chemotherapy of 62% for carcinosarcomas and 83% for epithelial ovarian cancers, with median PFS of 11 versus 16 months and median OS of 24 versus 41 months (441). Current GOG trials allow patients with carcinosarcoma of the ovary to participate in trials for carcinosarcoma of the uterus, and in the current front-line study, GOG #261, women with stage I-IV disease are randomized to either paclitaxel plus carboplatin or ifosfamide plus paclitaxel.

FOLLOW-UP OF PATIENTS WHO ARE CLINICALLY WITHOUT EVIDENCE OF DISEASE-SURVIVORSHIP ISSUES

There are relatively few studies of long-term effects of therapy for ovarian cancer. The majority of women who present with advanced-stage disease ultimately recur, and anxiety about recurrence is very common. Recent survey studies also identify sexual dysfunction, peripheral neuropathy, hearing loss or tinnitus, cognitive changes, gastrointestinal symptoms, fatigue, and insomnia as issues of great concern (443–445).

Matulonis et al. studied survivors of early-stage ovarian cancer and found that 90% had either no interest in sex or were not sexually active (446). In premenopausal women with ovarian cancer, the removal of the ovaries results in premature menopause. Consequently, they have symptoms including hot flashes and vaginal dryness, and those who achieve long-term survival are at increased risk for osteoporosis. There is some concern about prescribing HRT to ovarian cancer survivors because (1) epidemiologic evidence (described above) suggests that estrogen replacement therapy slightly increases the risk of developing ovarian cancer *de novo*, and (2) antiestrogens, such as tamoxifen, may produce tumor shrinkage in a small subset of women with advanced ovarian cancer. However, there is no evidence that hormone therapy increases the risk of recurrence. One small randomized, controlled trial reported that estrogen replacement therapy has no detrimental effect on disease-free or overall survival in women with ovarian

cancer (447). Short-term estrogen replacement therapy, particularly in symptomatic women who were premenopausal prior to their surgery for ovarian cancer, would appear reasonable. Screening for osteoporosis in women who have early-stage disease and do not opt for HRT is appropriate, since there are alternate treatments, such as raloxifene, bisphosphonates, or alendronate, available. Issues of sexual dysfunction may be related to side effects from surgery (scarring, shortening of the vagina) and feelings of anxiety as well as estrogen deprivation. HRT can relieve the estrogen deprivation-related symptoms and cancer support groups and/or qualified psycho-oncologic help can address the general anxiety. Refractory and bothersome sexual problems might require referral of women and their partners to practitioners with expertise in the area.

A group of Italian investigators reported on long-term neurologic evaluations in 120 ovarian cancer patients treated with a front-line carboplatin AUC5/paclitaxel 175 mg/m² regimen. There was a 15% chance of residual neuropathy 6 months after the completion of chemotherapy (448). This will be higher with more dose-intense (e.g., weekly) paclitaxel regimens such as the one recently published by the Japanese Gynecologic Oncology Group (JGOG, see “alternate paclitaxel dosing” above) and with cisplatin-containing regimens, which currently includes most intraperitoneal chemotherapy. While there are agents, such as duloxetine, that can provide some symptomatic alleviation (449) for neuropathy, it is best prevented. Patients should be questioned about numbness and tingling in their hands and feet at each visit during treatment, and agent substitution (e.g., docetaxel for paclitaxel, carboplatin for cisplatin) or dose modification should be considered before neuropathy becomes severe, particularly in patients whose life might be affected by neuropathy (e.g., piano player). Interestingly, neuropathy is the one symptom that has consistently been reported to be worse in elderly patients than in younger patients across studies.

Risks of second primaries, particularly for patients with a *BRCA* mutation or Lynch syndrome should be kept in mind. Patients may have been too overwhelmed at the time of diagnosis to consider genetic counseling, and other family members may develop cancers as time goes by, so the issue should be reconsidered during follow-up visits.

CA-125 Follow-Up of Patients in Remission

National Comprehensive Cancer Network (NCCN) Guidelines for follow-up of patients with ovarian cancer who enter a clinical complete remission (450) include a history and clinical exam every 2 to 4 months for 2 years, then 3 to 6 months for 3 years, then annually after 5 years, with CA-125 or other tumor markers at every visit if initially elevated, and imaging only as clinically indicated. Pelvic exam should be performed periodically. Unlike the situation in general screening (451), a rise in CA-125 in patients with high-grade serous cancers after primary treatment is fairly specific for recurrence, particularly if the pretreatment CA-125 was significantly elevated and a second confirmatory CA-125 shows that the titer is continuing to rise. The CA-125 may rise prior to any evidence of disease on imaging, and in about a third of all women over 6 months will elapse before they develop symptoms. Recurrent ovarian cancer is not curable, and it is not clear that earlier detection can improve either survival or quality of life. The Medical Research Council (OV-05) and the European Organization for the Research and Treatment of Cancer (EORTC 55955) conducted a phase 3 trial in which 1,442 women with a clinical complete remission after first-line platinum containing therapy were followed with serial CA-125 levels followed by randomization to either initiate treatment at the time of biochemical recurrence (defined as a CA-125 exceeding twice the upper limit of normal) versus waiting until the time of clinical evidence of recurrence. Five hundred twenty-nine women were randomized.

Twenty percent of women had a rise in CA-125 within 6 months of completing primary chemotherapy, 33% between 6 and 12 months, and 45% after 12 or more months. Treatment at the time of CA-125 rise resulted in starting chemotherapy 4.8 months earlier compared to patients treated at the time of clinical recurrence. However survival (defined as survival from the time of CA-125 rise) did not differ between the 2 groups, at 25.7 months for women assigned to early treatment, and 27.1 months for those assigned to delayed treatment. Most importantly, women receiving early treatment had a worse quality of life as measured by a shorter time to deterioration of the global health score on the EORTC QLQ-C30 questionnaire (452). Issues concerning the use of CA-125 as part of follow-up should be discussed with patients. Detection of disease while it is not symptomatic may allow patients more opportunity to participate in trials of new agents, but it cannot be claimed to improve survival, and some women may opt for less aggressive monitoring.

USES OF CA-125 IN OVARIAN CANCER TREATMENT

Tumor markers in general are discussed in Chapter 6. As discussed above, the current usefulness of CA-125 for screening of asymptomatic women is limited, in part because many stage I ovarian cancers are not associated with an elevated serum level of CA-125, and a variety of nonmalignant conditions (endometriosis, tuberculosis, abdominal infections, hepatitis) can elevate CA-125, particularly in premenopausal women. Current large-scale screening trials use a ROCA (risk of ovarian cancer algorithm) which establishes a CA-125 baseline for each woman and screen for changes in slope (453). Results of these trials are awaited. Newer markers such as human epididymis protein 4 (HE4) and CA72.4 are not influenced by the hormonal fluctuations of the menstrual cycles, but have not been shown to improve overall outcomes for screening although they might increase specificity (454). HE4 is FDA-approved as part of the ROMA (risk of malignancy algorithm) used to determine the likelihood of malignancy of an indeterminate adnexal mass. CA-125 is also widely used to monitor for cancer recurrence in patients with complete remission after front-line therapy, but as described above, this has not been shown to improve survival. For women with a high CA-125 at baseline, the marker correlates with volume of disease, and is often checked with each cycle of chemotherapy. Multiple studies have shown that the rapidity of CA-125 normalization and depth of CA-125 nadir after completion of primary therapy have prognostic value. For example, one group found median progression-free and overall survival for women with stage III or IV ovarian cancer who achieved a value of less than 35 U/mL after third cycle to be 18 months and 42 months respectively, compared to 9 months and 22 months for patients whose tumor marker did not normalize ($p < 0.001$) (314). The authors suggested that in future trials women whose CA-125 does not normalize after the third cycle should be switched to an alternate regimen. However, at this time there are no clinical interventions known to improve outcomes for those women who do not show the desired decline in CA-125.

CA-125 may be useful for monitoring the effectiveness of second-line chemotherapy, decreasing the need for frequent imaging. A number of CA-125 response definitions, such as 50% or 75% decline, have been developed (455). Herzog et al. reported that in a large phase III ovarian cancer trial of salvage chemotherapy (OVA-301, pegylated liposomal doxorubicin plus trabectedin versus pegylated liposomal doxorubicin alone) the concordance between CA-125 using modified Rustin criteria (which define a CA-125 response as $\geq 50\%$ reduction in CA-125 levels from pretreatment values, maintained at least 28 days) (456,457) and RECIST (Response Evaluation Criteria in Solid Tumors

1.0) criteria was 79%. The negative predictive value of CA-125 was 89% to 90%, indicating that in most cases lack of CA-125 response predicts lack of radiologic response. However, the positive predictive value of CA-125 was only 59% to 68%, indicating that response by CA-125 does not always predict a RECIST response. Changes in CA-125 tended to occur first: radiologic response was preceded by a CA-125 decrease in a high proportion of patients, and CA-125 progression preceded RECIST progression in 35% of patients, with a median lead time of 8.4 weeks (458).

Caution should be used when relying on CA-125 to assess response to therapy, particularly in women with heavily pretreated disease. It can occasionally happen that major discordance develops, and the cancer progresses while the CA-125 value declines. In addition, caution should be used in discontinuing a therapy after the first cycle of chemotherapy based solely on rise in CA-125. Sabbatini et al. reported that only half of the patients who eventually had a CA-125 decline with liposomal doxorubicin therapy had a decline prior to the second cycle of therapy (459). Questions have also been raised as to whether CA-125 response criteria are valid in the setting of anti-VEGF targeted therapy, since it has been noted that patients on maintenance bevacizumab were noted to sometimes have clinically stable disease for a prolonged period after a rise in CA-125 that would have qualified as progression (460). It is unclear if the issue is unreliability of CA-125, or ability of the targeted agent to provide continued benefit even in the setting of slight tumor growth. Removal of ascites will affect CA-125 levels; renal dysfunction does not (461).

TREATMENT OF PERSISTENT/RECURRENT DISEASE

Ovarian cancer that is resistant to primary chemotherapy or recurs at some point after primary chemotherapy is generally not curable. Nonetheless, some women with recurrent disease will have prolonged survival. Of the women who are not cured by their primary therapy, about 10% will progress on primary platinum treatment, and are described as having disease that is “platinum-refractory,” about 15% will progress 0 to 6 months after completion of completion of primary therapy and are said to have “platinum-resistant” disease, and 75% have disease that recurs more than 6 months after primary therapy, which is termed “platinum-sensitive” (462–464).

Secondary Cytoreductive Surgery

Surgery in the treatment of recurrent ovarian cancer is covered in the Section “Surgery”. It is generally considered indicated when the cancer recurs a prolonged time after primary therapy and/or in a limited site. Two current randomized trials, GOG #213 and the DESKTOP III trial, are addressing whether surgery plus chemotherapy improves survival over chemotherapy alone in women with platinum-sensitive recurrent disease.

Second-Line Chemotherapy

In 1991 Markman et al. published an influential retrospective review of 72 patients who had responded to initial platinum-based therapy and were subsequently retreated with a platinum-based regimen (465). The response rate for women with a “platinum-free interval” of 5 to 12 months was 27%, for 13 to 24 months was 33%, and for over 24 months was 59%. Women who had a greater than 24-month interval with no therapy (as opposed to just no platinum-based therapy) had a 77% response rate with a 32% rate of surgically confirmed complete

remission. Subsequent clinical trials have generally be conducted separately for patients with tumors classified as “platinum-resistant”, usually meaning progressive disease less than 6 months after most recent platinum dose and those with tumors classified as “platinum-sensitive,” usually meaning progression more than 6 months after most recent platinum dose. The term “platinum-refractory” usually refers to disease with less than a CR to primary platinum therapy, although it can also be used for disease that progresses on any line of platinum therapy.

As a general rule, the platinum-free interval after first treatment is predictive for overall survival as well as response to chemotherapy, including nonplatinum chemotherapy. In a randomized trial of pegylated liposomal doxorubicin (PLD) versus PLD plus trabectedin as first salvage chemotherapy, the overall survival was 13.6 months for women with a platinum-free interval of less than 6 months, 20.3 months for those with a platinum-free interval of 6 to 12 months, and 32.5 months for those with a platinum-free interval of over 12 months (466). An exception to this general rule may be the small fraction of women with advanced-stage low-grade serous tumors whose disease is slower growing, but not generally very chemotherapy sensitive. Women with high-grade tumors whose disease has less than a partial response to primary platinum plus taxane therapy have a very poor prognosis, and response to any subsequent treatment is unlikely.

While categories of “platinum sensitivity” are useful shorthand predictors of the likelihood of response to further treatment, they have primarily been created for use in clinical trials and must be used with clinical judgment when selecting therapy in individual cases. For example, a woman with stage I clear cell carcinoma that recurs with diffuse disease 7 months after completion of adjuvant chemotherapy probably had no response to treatment at all, and her cancer will likely be refractory to further chemotherapy. On the other hand, a woman with suboptimally debulked stage IV serous carcinoma that has responded completely to primary chemotherapy and who has a rise in CA-125 5 months later, probably has chemotherapy-sensitive disease, and is very likely to have at least some tumor shrinkage with a second line of treatment.

Time since most recent platinum therapy is not the only means of predicting benefit from future treatment. Eisenhauer et al. analyzed results for 704 patients who had recurrence or persistent disease after primary platinum-based therapy and were treated on a variety of second-line chemotherapy trials (467). Independent predictors of a positive response to second-line therapy were a largest tumor diameter of less than 5 cm, fewer sites of disease, and serous histology. Time to recurrence since primary therapy, when analyzed as a continuous variable, was not independently prognostic, and was closely correlated with tumor size. Lee et al. published a nomogram for predicting progression-free survival in women with platinum-sensitive recurrent ovarian cancer. The most important factor contributing to shorter progression-free survival was size of the largest tumor; other descriptors remaining significant in multivariable analysis were platinum-free interval, CA-125 (higher values being worse), number of organ sites of metastasis, and white blood count (higher being worse) (468). The effects of prolonged consolidation therapy on future sensitivity of the tumor to treatment have not been well studied, and are likely to vary with the agent used.

Patients with a complete response to second-line platinum therapy will usually have a shorter time to recurrence after the second treatment regimen than after the first (469), and recurrent ovarian cancers eventually become resistant to platinum and all other chemotherapy agents. Hoskins et al. developed a statistic for estimating benefit from further therapy in patients who had received multiple regimens. Women with a time from first to third (or second to fourth, third to fifth, etc.) relapse or progression of 6 months or less had a median survival of under 3 months. In other words, women with minimal or no benefit (with prolonged disease stabilization considered a benefit)

from 2 different therapies in a row have a very poor prognosis (470). This is in line with the current American Society of Clinical Oncology (ASCO) recommendation that cancer-directed therapy should, in general, not be used for patients who have low performance status and have not had benefit from prior evidence-based interventions (471).

Platinum-Sensitive Disease

Single Agent Cytotoxic Therapy in

Platinum-Sensitive Disease

Response rates in multicenter trials testing single-agent cisplatin or carboplatin in women with platinum-sensitive disease are generally 30% to 50% (472,473), and, as discussed above, tend to be higher in women with a longer platinum-free interval. Response rates in multicenter trials to single-agent paclitaxel, topotecan, or liposomal doxorubicin in platinum-sensitive disease have generally been in the range of 20% to 35% (472,474). Platinum agents are the most active front-line drugs for the treatment of ovarian cancer and are generally considered to be the most active agents in women with platinum-sensitive relapsed disease, particularly for women who relapse more than 12 months after completing primary therapy. However, there are very few randomized data directly comparing single-agent platinum compounds to other single agents in women with platinum-sensitive disease. The EORTC randomized 86 women to either single-agent paclitaxel or single-agent oxaliplatin. Responses among the 63 platinum-resistant patients were 5 out of 31 (16%) for paclitaxel and 2 out of 32 (6%) for oxaliplatin. Responses among the platinum-sensitive patients were 2 out of 10 (20%) for paclitaxel and 5 out of 13 (38%) for oxaliplatin (475).

Platinum-Based Combination Cytotoxic Therapy in Platinum-Sensitive Disease

Results of several retrospective analyses of carboplatin/paclitaxel combination therapy in women with platinum-sensitive disease showed strikingly high response rates of 70% to 90% (476,477), and raised the question of whether combination therapy was superior to single-agent therapy in this setting. There have been several randomized trials comparing platinum-based combination cytotoxic therapy to single-agent platinum therapy (472,473,478) (Table 24.16). In general, these show superior response rates and superior progression-free survival with combination therapy. Results regarding overall survival are conflicting. Only the ICON4/AGO-OVAR-2.2, a combined analysis of 2 parallel trials comparing paclitaxel plus platinum to “conventional platinum-based chemotherapy” (71% received single-agent carboplatin, 17% cisplatin/doxorubicin/cyclophosphamide, and 12% other nontaxane platinum-based regimens), showed convincing survival benefit; the absolute improvement in overall survival was 5 months (from 24 months to 29 months) (389). Only about 40% of the patients in this analysis had received prior taxane therapy, and this has raised concern about the generalizability of the results although there was no significant statistical interaction between survival benefit and prior taxane therapy. It was noted that only 31% of patients in the nontaxane arm received taxane therapy at the time of progression. Other trials have not shown a survival benefit to combination chemotherapy in women with platinum-sensitive disease. The GCIIG trial randomizing women to carboplatin and to carboplatin plus gemcitabine was not powered to show an overall survival difference; however, despite a superior response rate (complete response was achieved in only 6% of women on single agent therapy versus 15% of women on the combination regimen) and a longer progression-free interval with combination treatment, there was no evidence of a trend to survival benefit (473). There were no differences in quality of life scores

Table 24.16 Combination Cytotoxic Therapy in Platinum-Sensitive Recurrent Ovarian Cancer

Author (yr)	n	Regimen	RR	Median PFS	Median OS
Bolis (2001) ⁵⁵⁴	190	Carboplatin	56%	3 yr	3 yr
		Carboplatin +	62%	12%	29%

between the 2 arms; the primary difference in toxicities was increased hematologic toxicity of the combination regimen, with 27% versus 8% grade 3/4 anemia, 70% versus 12% grade 3/4 neutropenia, and 35% versus 11% grade 3/4 thrombocytopenia.

Several trials in women with platinum-sensitive disease have compared platinum-based combinations to each other. Most notably the CALYPSO trial compared carboplatin AUC 5 plus pegylated liposomal doxorubicin (PLD) 30 mg/m² every 4 weeks to carboplatin AUC 5 plus paclitaxel 175 mg/m² every 3 weeks, and showed superior PFS for the PLD regimen. Again, toxicities differed: the PLD regimen produced less alopecia and neuropathy, but more nausea, mucositis, and hand-foot syndrome (479). The HECTOR trial, which has been reported only in abstract form, compared carboplatin AUC 5 plus topotecan 0.75 mg/m² days 1,2,3 every 3 weeks with standard therapy consisting of physician/patient choice of either carboplatin plus paclitaxel, carboplatin plus gemcitabine, or carboplatin plus pegylated liposomal doxorubicin. 78% of patients in the standard therapy group chose gemcitabine plus carboplatin. There was no

significant difference in response rate, progression free survival, or overall survival between the 2 arms (480).

Platinum-Resistant Disease

In general, tumors resistant to platinum are more resistant to any cytotoxic agent. A number of phase 3 randomized trials including paclitaxel (474), topotecan (474,481), pegylated liposomal doxorubicin (474), and gemcitabine (482) as single agents have been informative in guiding our treatment of platinum-resistant disease. They show that response rates to conventional single-agent therapy in this group of women are about 10%, median progression-free survival is about 3 to 4 months, and median overall survival is 9 to 12 months. Significant differences in terms of response rate or survival between various agents in platinum-resistant disease are not usually seen.

Combinations of cytotoxic agents have not been shown to be superior to single agent therapy in women with platinum-resistant disease. A small trial randomized 234 women whose

disease had recurred within 12 months of initial platinum-based therapy (median, 3 months) to single-agent paclitaxel versus epirubicin plus paclitaxel (483). The response rate was 37% for the combination and 47% for single-agent paclitaxel; median survival was 12 months and 14 months, respectively. A small randomized phase II GINECO (Groupe d'Investigateurs Nationaux pour l'Etude des Cancers Ovariens) trial comparing single agent weekly paclitaxel to weekly paclitaxel plus carboplatin or weekly paclitaxel plus weekly topotecan in patients with platinum-resistant ovarian cancer showed no improvement in response rate or PFS with combination therapy (484). A randomized trial of trabectedin plus pegylated liposomal doxorubicin versus pegylated liposomal doxorubicin alone showed that in women with platinum sensitive disease both disease response rates and progression-free survival were improved (35% versus 23%; 9.2 versus 7.5 months), whereas for women with platinum-resistant disease they were not (12% versus 13%; 3.7 versus 4.0 months) (485). On the basis of these results, trabectedin plus PLD was approved for the treatment of women with platinum sensitive relapsed ovarian cancer in the European Union, although not by the U.S. Food and Drug Administration (U.S. FDA).

In summary, platinum-based combinations improve response rates and progression-free survival and have become the usual treatment in the United States as the first salvage regimen for women who relapse more than 12 months after the completion of primary therapy, with single-agent therapy usual in women who have an initial treatment-free interval of less than 6 months, and individualized decisions in those with a 6- to 12-month treatment-free interval. Treatment is not curative, and there are situations in which a patient with late relapse may choose single agent or nonplatinum therapy; it is unlikely that survival is significantly compromised by such a choice.

Drugs Useful in Treatment of Recurrent Ovarian Cancer

Taxanes, liposomal doxorubicin, topotecan, and gemcitabine have been studied in randomized trials, as discussed above. They are discussed in slightly more detail below. A number of other agents are occasionally useful. Hexamethylmelamine (altretamine) is an older alkylating agent with the advantages (patient convenience) and disadvantages (inappropriate for patients with episodic or partial small bowel obstruction, limited availability for patients without good insurance coverage for outpatient medication) of an oral therapy. It is rarely used, as it produces significant amounts of neuropathy, nausea, and vomiting. A GOG phase 2 trial of single-agent hexamethylmelamine in women with platinum-resistant ovarian cancer demonstrated a 10% response rate and a 21% rate of grade 3 emesis (486). Oral etoposide, a topoisomerase II inhibitor, is better tolerated and may be slightly more active. It is leukemogenic, which has limited enthusiasm for attempts to incorporate it into front-line therapy, but it remains a useful salvage agent. Interestingly, intravenous etoposide appears to have minimal activity in women with pretreated ovarian cancer. Ifosfamide has produced response rates of 10% to 20%, but the toxicities, hematologic and neurologic, are excessive compared to those of other available agents, and it is rarely used (487). Irinotecan is associated with substantial diarrhea and nausea, which can be particularly troublesome in ovarian cancer patients with some preexisting level of bowel dysfunction; it will hopefully be better tolerated as part of the ongoing front-line international trial for clear cell carcinoma. Vinorelbine, capecitabine and pemetrexed (488) may sometimes be useful; none of them are FDA approved for use in ovarian cancer.

Taxanes

Although in most parts of the world taxane therapy is now part of front-line treatment for ovarian cancer, taxanes remain very useful in treating recurrent disease. Both weekly paclitaxel (489,490)

and docetaxel (491) have shown response rates of 20% to 30% in women who recurred within 6 months of primary platinum-taxane-based combination therapy. Weekly paclitaxel is particularly useful, as it tends to be less myelotoxic than many other regimens. Nab-paclitaxel is a newer taxane with the advantage that it does not require steroid premedication to avoid hypersensitivity reactions. Nab-paclitaxel on a schedule of 100 mg/m² days 1, 8, 15 on a 28-day schedule produced a response rate of 23% in women with platinum/paclitaxel resistant ovarian cancer (492).

Topotecan

Topotecan, a topoisomerase I inhibitor, is FDA-approved for the treatment of recurrent ovarian cancer, and as discussed above, is as effective as or more effective than paclitaxel or liposomal doxorubicin in women with platinum-resistant disease. In a phase III trial comparing IV topotecan on the FDA-approved schedule of 1.5 mg/m²/day × 5 days to oral topotecan at a dose of 2.3 mg/m²/day × five days every three weeks in women with ovarian cancer, the response rate to intravenous topotecan for women with platinum-refractory disease was 5% and the response rate for women with platinum-resistant disease was 11% (493). However, the daily × 5 regimen is not convenient and has proved more myelosuppressive than most treating physicians deem reasonable in the palliative setting. Lower starting doses of 1.0 to 1.25 mg/m² are better tolerated, although their efficacy is not as well documented. Individuals at increased risk for myelotoxicity include those with impaired renal function, older age, extensive prior therapy, or prior pelvic irradiation.

Weekly bolus topotecan has been shown to have some activity in a number of small trials, and has come into common use because the schedule is convenient and produces less myelosuppression (494). The maximum tolerated dose (MTD) in phase 1 studies was 4 mg/m² with dose-limiting toxicities of anemia, chronic fatigue, and gastrointestinal distress. A randomized phase 2 trial of topotecan 4 mg/m², given 3 weeks out of 4 versus topotecan 1.25 mg/m² daily × 5 in 194 women with platinum-resistant ovarian cancer showed a numerically lower response rate for the weekly schedule (2 of 28 vs. 5 of 21 for the daily × 5 regimen) as well as a nonsignificantly decreased PFS (3.0 vs. 4.4 months). Overall survival was similar (9.6 vs. 9.3 months) (495). It is possible that difference between the 2 schedules would be more evident in patients with platinum sensitive disease. The GOG attempted to randomize women with platinum sensitive disease to a weekly versus daily regimen, but enrollment was slow, and the trial was changed to a single arm phase II trial of weekly topotecan. The response rate for the 15 patients receiving the daily × 5 regimen was 27%, but the confidence intervals around this response rate were very wide given the small number of patients; response rate for the 65 women receiving the weekly regimen was 12% (496).

Liposomal Doxorubicin

Liposomal doxorubicin is also FDA approved for the treatment of recurrent ovarian cancer. The every-4-week schedule of administration is convenient, and the lack of alopecia is attractive to patients. However, there is a high incidence of palmar-plantar erythrodysesthesia using the approved dose of 50 mg/m². Markman et al. published a nonrandomized phase 2 trial suggesting that there was only a 12% incidence of grade 2 and no grade 3 palmar-plantar erythrodysesthesia when the starting dose was lowered from 50 mg/m² to 40 mg/m². The response rate was 9%; all patients were platinum/paclitaxel resistant with a median of 2 prior regimens (497). It is not known if doxorubicin or epirubicin would have similar activity; these drugs have well-documented activity in ovarian cancer, mostly in the front-line setting, but a very different side effect profile. One small phase II trial reported a response rate of 18%

to epirubicin at a dose of 150 mg/m² in women with platinum-resistant ovarian cancer (467).

Gemcitabine

As discussed above, gemcitabine has modest activity in the treatment of recurrent ovarian cancer. Based on experimental models, it was hypothesized that combining gemcitabine with cisplatin might reverse platinum resistance. Cisplatin-resistant cells upregulate nucleotide excision repair complexes, which are thought to be inhibited by gemcitabine. Preclinical models suggested synergy between cisplatin and gemcitabine in platinum-resistant cell lines. A multicenter GOG trial of the combination as second-line therapy in women with platinum-resistant ovarian cancer reported a response rate of 16% (498).

Bevacizumab

Elevated vascular endothelial growth factor (VEGF or VEGF-A) expression occurs in all stages of ovarian cancer and is associated with poor prognosis, including shorter survival. In addition, VEGF (which is also known as vascular permeability factor) overexpression is directly associated with the production of ascitic fluid.

Bevacizumab is a humanized anti-VEGF monoclonal antibody. Prospective trials have reported activity of single-agent bevacizumab against pretreated ovarian cancer to be in the range of 15% to 20%. It is generally well tolerated; however, notable toxicities include hypertension, proteinuria, excess venous thrombosis, and bowel perforation and fistulization. The GOG evaluated single-agent bevacizumab in 63 patients treated with one to 2 prior regimens of cytotoxic chemotherapy who had recurred within 12 months of treatment with a platinum agent. The overall response rate was 21% with a median response duration of 10 months (499). Twenty-five of 62 patients had a progression-free survival (PFS) of ≥ 6 months. Cannistra et al. evaluated 44 patients with platinum-resistant disease that had progressed after second-line topotecan or liposomal doxorubicin. The overall response rate was 16% (7 out of 44) (500). This study closed early due to the higher than expected number of gastrointestinal perforations (5 out of 44), 1 of which was fatal. Since that time, most trials with bevacizumab exclude patients with evidence of bowel obstruction or bowel invasion by tumor. Another trial evaluated the combination of bevacizumab and metronomic (daily low-dose) oral cyclophosphamide in 70 women who had been treated with up to 3 prior chemotherapy regimens. Fifty-six percent of patients were progression-free at 6 months and the overall response rate was 24% (501). The response rate for women with platinum sensitive disease was higher than the response rate for women with platinum-resistant disease (33% versus 12%) although the difference was not statistically significant. The cyclophosphamide in this regimen was postulated to have an antiangiogenic effect. Interestingly, a subsequent study in women with heavily pretreated ovarian cancer (a median of 4 prior regimens) and known *BRCA* mutations reported a response rate to single agent oral cyclophosphamide of 13% (502).

Recent interest has focused on combinations of bevacizumab and cytotoxic agents. Trials in both platinum-sensitive and platinum-resistant disease have shown improvements in response rate and progression-free survival when bevacizumab is combined with standard therapy. The OCEANS trial (Table 24.14) was a randomized, double-blind placebo controlled trial comparing the combination of gemcitabine plus carboplatin plus bevacizumab to the combination of gemcitabine plus carboplatin plus placebo in women with platinum sensitive recurrent ovarian cancer. Chemotherapy was continued for a planned 6 cycles, or up to ten cycles in patients with continued response. After completion of chemotherapy, bevacizumab or placebo were continued until progression. Overall response rate and median progression-free survival were both significantly improved with

the addition of bevacizumab (78%; 12.3 months versus 57%; 8.6 months). Overall survival data were immature at the time of publication, but, as is the case with front-line therapy, there was no apparent difference between the arms, at 33.3 months for the bevacizumab arm and 35.2 months for the placebo arm (503). The AURELIA trial (Table 24.14) was conducted in platinum-resistant patients; results have been presented in abstract form (504). 361 women with platinum-resistant ovarian cancer and one or two prior regimens were randomized to standard therapy, consisting of investigators choice of pegylated liposomal doxorubicin, topotecan, or weekly paclitaxel, with or without bevacizumab. Patients in the chemotherapy arm were permitted to cross over to bevacizumab monotherapy at the time of progression. Overall response rate was significantly improved from 12.6% to 30.9% and progression-free survival was improved from 3.4 months to 6.7 months by the addition of bevacizumab.

Platinum Hypersensitivity

Repeated courses of carboplatin therapy place patients at risk for hypersensitivity reactions. These reactions usually occur during drug infusion and are associated with flushing, nausea, and hypertension. They may be severe and/or fatal. Atypical hypersensitivity reactions, occurring after drug infusion, have also been described (505). A number of desensitization protocols have been published and appear to be generally effective (506); they often involve premedication with steroids and antihistamines, and starting infusions very slowly then gradually increasing the rate over 4 to 24 hours. These regimens are inconvenient and should be used primarily in patients who are likely to benefit from platinum treatment and who do not have good alternate treatment options. Not all patients allergic to carboplatin will be allergic to cisplatin. Interestingly, hypersensitivity reactions have been reported to be lower with some second-line combinations than others. The HECTOR trial reported the rate of hypersensitivity reactions to be 15% with topotecan plus carboplatin, 12.7% with paclitaxel plus carboplatin, and only 8.5% with gemcitabine plus carboplatin (480). The CALYPSO trial reported rates of hypersensitivity to be lower with the combination of liposomal doxorubicin plus platinum (15.5%, with 2.4% $>$ grade 2) than with the combination of paclitaxel plus carboplatin (33.1%, with 8.8% $>$ grade 2) (507). Interestingly, elderly patients in this study had a significantly decreased risk for hypersensitivity reactions (508). Weekly carboplatin may be associated with an increased risk for hypersensitivity reactions. One phase II trial of weekly docetaxel and carboplatin reported that 33% of patients discontinued therapy because of hypersensitivity reactions. Routine use of diphenhydramine premedication was reported to produce a nonsignificant decrease in the rate of these reactions (509).

Hormonal Therapy

Epithelial ovarian cancers frequently express estrogen and progesterone receptors, and higher levels of PR expression are associated with lower-grade and improved survival (169). Multiple attempts have been made to treat ovarian carcinoma with hormonal therapy, including progestins, antiestrogens, and gonadotropin-releasing hormone (GnRH) analogs. The response rates generally are quite low, in the range of 10% (510). Many of the trials were performed decades ago, before steroid receptor analysis was available, and the role of steroid receptors in predicating response of ovarian carcinomas to hormonal therapy remains unclear. Over 90% of serous borderline ovarian tumors are estrogen-receptor positive (371), and there are case reports of responses to tamoxifen, leuprolide, and anastrozole. The MD Anderson group retrospectively reviewed outcomes to various hormonal therapy regimens in 133 women with recurrent low-grade serous carcinomas and found a 9% response rate (372).

Progestins/Antiproggestins

A review of 13 trials of 10 patients or more (432 patients total) treated with progestins (medroxyprogesterone acetate or megestrol acetate) revealed a major response rate of 7.2%, with stable disease in 10.9%. Progestins have well-documented activity in the treatment of recurrent endometrial carcinoma, and it has therefore been hypothesized that they will have activity in the endometrioid subset of ovarian cancers, which tend to express high levels of progesterone receptors. A series of 43 patients with ovarian endometrioid carcinoma who used medroxyprogesterone acetate as first-line therapy postsurgery or postradiotherapy was reported in 1982. Eighty-four percent of the patients had well-differentiated disease. Forty-one of them underwent second-look laparotomy after 6 to 8 months of therapy. Twenty-three had evidence of tumor regression and 8 had no evidence of disease. Tumor regression was observed in 68% of the 31 cancers that were positive for both estrogen receptor (ER) and PR and in none of the cancers that did not express either receptor (511). In one phase 2 study of megestrol acetate in 36 platinum-refractory ovarian cancer patients, 3 complete responders were observed; all had tumors of endometrioid histology (512).

RU486 (mifepristone) is a synthetic antiprogesterin that competitively binds the progesterone receptor (as well as the glucocorticoid receptor) and inhibits ovarian cancer cell growth *in vitro*. Rash tends to be the limiting toxicity. One phase 2 trial using RU486 in the treatment of platinum-resistant ovarian cancer patients reported a 26.5% response rate, including one complete response of over 3 years' duration, but a more recent GOG trial found a response rate of only 4.5% (one of 22).

Estrogens and tamoxifen have the ability to upregulate progesterone receptor expression, and have therefore been used to try to improve the benefit observed with progestin therapy. Two trials treated women with sequential ethinyl estradiol 50 µg per day and medroxyprogesterone acetate 200 mg per day with response rates of 14% and 17% (513,514). Some patients required dose reduction of the ethinyl estradiol because of severe nausea. Two trials have also treated women with sequential tamoxifen and progestins; no responses were observed.

Tamoxifen

Tamoxifen is a selective estrogen receptor modulator (SERM) with estrogen agonist activity on some tissues (such as bone) and antagonist activity on breast cancers. One review of 18 trials testing tamoxifen in the treatment of advanced ovarian cancer, with a cumulative total of 648 patients, found an overall 13% response rate (515). There was marked heterogeneity in the response rates, suggesting that selection bias (for unknown factors) may be very important. A randomized controlled trial comparing tamoxifen to triptorelin showed no responses in either arm (516). In the 1980s the GOG conducted a trial of tamoxifen 20 mg po bid (twice the dose commonly used in the treatment of breast cancer) in 105 women with previously treated ovarian cancer. There was an overall 17% response rate, including 13% complete responses. Median duration of response was 4.4 months. Eight of the 9 patients achieving a complete response had elevated levels of estrogen receptor (517). However, the difference in response by estrogen receptor status was not statistically significant. It has been suggested that tamoxifen might be an appropriate therapy for women with small-volume asymptomatic recurrences. The GOG completed a randomized trial comparing tamoxifen to thalidomide for the therapy of women who have CA-125 marker elevation but no measurable recurrence of disease. Women treated with thalidomide had a median progression-free survival of 3.2 months versus 4.5 months for those treated with tamoxifen, which may suggest some benefit for tamoxifen (518).

GnRH Agonists

GnRH receptors are expressed on about 80% of ovarian cancers. A summary of 12 published trials using GnRH agonists in women with recurrent ovarian cancer noted an overall 5.7% response rate and a disease stabilization rate of 21% with only one complete responder (510). In the largest trial, which was conducted by the EORTC, there were no responders among 68 evaluable patients. Like other hormonal therapies, GnRH agonists have been suggested to have activity against stromal tumors. Of 12 patients treated in 4 reports of the use of GnRH agonists for ovarian granulosa cell tumors, there were 4 patients with a partial response and 4 with stable disease (510). A novel attempt at therapy is linking a chemotherapy to a GnRH agonist, and at least one agent with this design, AEZS-108 has entered clinical trials (519).

GnRH antagonists cause rapid suppression of gonadotropin secretion without the initial gonadotropin release caused by GnRH agonists. There has been one trial of the GnRH antagonist cetrorelix in 17 patients with ovarian or müllerian carcinoma refractory to platinum chemotherapy. Three patients (18%) experienced a partial remission (520).

Aromatase Inhibitors

The major source of estrogen (principally estrone) in postmenopausal women is aromatization of androstenedione in the skin and adipose tissues. Commercially available third-generation aromatase inhibitors include anastrozole, letrozole, and exemestane. Five phase 2 trials of aromatase inhibitors reported 7 major responses among 179 patients with measurable disease by RECIST criteria (4%) and 16 CA-125 responses among 124 patients with CA-125 evaluable disease (13%) (510).

Androgen/Antiandrogen Therapy

About half of ovarian cancers have been reported to express the androgen receptor. Two studies of androgen therapy did not report any objective responses. Two small studies of the nonsteroidal antiandrogen flutamide noted response rates of 4.3% and 8.7% and disease stabilization rates of 8.7% and 28% (510).

NEW THERAPEUTICS

Targeted therapy

It has been increasingly recognized that low-grade serous cancers, clear cell cancers, and mucinous cancers represent tumors that are biologically very different from high-grade serous cancers, and trials in ovarian cancer have begun to "target" by histologic subtype. The regimen of oxaliplatin/capecitabine with or without bevacizumab is being tested in an international first-line trial for mucinous carcinomas, and a front-line phase III international trial in clear cell carcinoma testing the combination of cisplatin and irinotecan has completed accrual. Given the genetic similarities of kidney cancer and clear cell ovarian cancer, temsirolimus and sunitinib, which are FDA-approved for use in kidney cancer, are being tested in trials specifically for clear cell ovarian cancer. While the response rate in the GOG phase II trial of temsirolimus in women with epithelial ovarian cancer unselected for histology was disappointing at 9.3%, one of the 3 patients with clear cell histology did have a partial response lasting 4 months.

With the exception of antiangiogenic agents (see below) studies in ovarian cancer with what are traditionally considered "targeted therapies" have not yet resulted in any approved agents. For example, detectable expression of EGFR has been reported

in 19% to 92% of ovarian cancers (521), with studies suggesting that EGFR dysregulation is associated with worse survival. However, separate phase 2 trials of the anti EGFR monoclonal antibodies, cetuximab and matuzumab were both negative (522,523), and 4 phase 2 trials using single-agent anti-EGFR small molecule tyrosine kinase inhibitors (3 with gefitinib and one with erlotinib) reported response rates of 0% to 6% (522,524–526). Interestingly, the trial with erlotinib did report that patients with any grade rash had a significantly longer survival than those without (9.9 vs. 3.6 months, $p = 0.009$), which is consistent with what has been observed in other disease sites (521), and one of the trials with gefitinib noted that the only patient with a partial response was also the only one found to have an EGFR mutation. Finally, as noted above, the EORTC/GCIG randomized phase 3 trial of erlotinib for 2 years versus observation in women with responding or stable disease after first-line platinum-based therapy did not show any benefit to the erlotinib.

A role for HER2 targeting therapy in ovarian cancer has also been explored. The GOG found that 11.2% of women with progressive or recurrent ovarian cancer had tumors that stained 2+ or 3+ for HER2 (527). However the response rate to the anti-HER2 monoclonal antibody trastuzumab in this group of women with 2+ or 3+ expression by immunohistochemical evaluation was only 7.3%. Gene amplification was not assessed in this study, and it is possible that therapy would be more effective in HER2-amplified disease, as it is in breast cancer, but this comprises a small subset of ovarian cancers. A recent report found HER2 amplification of 6/33 (18%) of mucinous ovarian carcinomas, and described one dramatic response to the combination of trastuzumab plus carboplatin in this usually chemotherapy-resistant tumor. Pertuzumab is a monoclonal antibody that binds to an epitope on HER2 distinct from the trastuzumab-binding site, and prevents dimerization of HER2 with other receptors. It has recently been approved by the U.S. FDA for treatment of HER2 positive metastatic breast cancer in combination with trastuzumab. A randomized phase 2 trial tested 2 different doses of pertuzumab in heavily pretreated ovarian cancer patients (median of 5 prior chemotherapy regimens). Five of 123 had a partial response (528). A subsequent trial that randomized women with platinum-resistant ovarian cancer to gemcitabine or gemcitabine plus pertuzumab showed a 5% response rate for gemcitabine versus 14% for the combination (529).

High frequency “druggable” mutations that would be analogous to the BCR-ABL gene in CML do not appear to exist in ovarian cancer. The Cancer Genome Atlas project analyzed messenger RNA expression, microRNA expression, promoter methylation and DNA copy number in 489 high-grade serous ovarian adenocarcinomas and the DNA sequences of exons from coding genes in 316 of these tumors. High-grade serous ovarian cancer is characterized by multiple mutations, with an average of 61.9 per tumor (530). Almost all tumors (96%) have TP53 mutations, but there were no other high-prevalence mutations found. A few low prevalence but statistically recurrent somatic mutations in genes including NF1, BRCA1/2, RB1 and CDK12 were described. Pathway analyses suggested that homologous recombination is defective in about half of the tumors analyzed, and this may help direct development of some agents, such as PARP inhibitors (see section on risk factors for a discussion of “synthetic lethality”). Investigators are working to develop algorithms to define so-called “BRCA-ness” of ovarian cancers in women who do not carry a mutation, but none have come into clinical use (326).

PARP Inhibition

A number of PARP [poly (ADPribose) polymerase] inhibitors have been under clinical development. The rationale for their use is discussed earlier, under Clinical features of BRCA-associated ovarian cancer. As single agents they appear to have significantly more *in vitro* activity against cell lines with BRCA1 or 2 deficiency than against wild-type cell lines. Olaparib (AZD2281) has been the most widely tested in ovarian cancer to date. Several studies have evaluated olaparib monotherapy in women with recurrent advanced epithelial ovarian cancer. Gelmon et al. treated 64 women with measurable ovarian cancer with single agent olaparib at a dose of 400 mg orally twice a day. One hundred ninety-six participants had a median of 3 prior chemotherapy regimens. Confirmed objective responses were observed in 41% of patients with BRCA1 or BRCA2 mutations, and 24% of women without mutations. Among women with platinum sensitive disease, responses were seen in 60% (3 of 5) BRCA1 or BRCA2 mutation carriers and in 50% (ten of 20) who did not carry a germline mutation; among women with platinum resistant disease responses were seen in 33% (4 of 12) BRCA1 or BRCA2

FIGURE 24.48. Single agent olaparib therapy. Best percentage change from baseline CA-125 concentrations, by platinum sensitivity and resistance.

Source: From Gelmon KA, Tischkowitz M, Mackay H, et al. Olaparib in patients with recurrent high-grade serous or poorly differentiated ovarian carcinoma or triple-negative breast cancer: a phase 2, multicentre, open-label, non-randomised study. *Lancet Oncol*. 2011;12(9):852–861, with permission.

mutation carriers but in only 4% (one of 26) women who did not carry a germline mutation (Fig. 24.48). The most common side effects were fatigue, nausea, and vomiting. All observed responses were partial responses, and the median overall progression-free survival was 219 days. Resistance to single agent therapy PARP inhibitor therapy usually develops in less than a year. Cancers in women with a germline *BRCA1* or *BRCA2* mutation can develop secondary genetic changes that restore the reading frame of the *BRCA* protein. Such secondary mutations are associated with the development of platinum-resistance and some similar mutation likely allows development of resistance to PARP inhibitors.

A randomized phase II trial of the oral PARP inhibitor olaparib (high or low dose) versus pegylated liposomal doxorubicin (PLD) in ovarian cancer patients with a germline *BRCA1* or *BRCA2* mutation who had recurred within 12 months of their most recent platinum-based regimen showed a median PFS of 8.8 months for the high-dose olaparib arm (400 mg twice a day), 6.5 months for the lower-dose olaparib arm (200 mg twice daily) and 7.1 months for the PLD group, which were not significantly different. The RECIST response rate was 31% in the high-dose olaparib arm and 18% in the PLD arm. One heavily pretreated patient receiving low-dose olaparib died of myelodysplastic syndrome. The PFS of 7.1 months seen with PLD exceeded that seen in a previous large randomized trial of patients with unknown *BRCA* status and similar proportions of patients with platinum-resistant and platinum-sensitive disease (4 months); it has been reported that patients with germline *BRCA1/2* mutations, derive more benefit from PLD treatment than women with nonhereditary ovarian cancers (531).

A randomized placebo-controlled phase II trial tested olaparib 400 mg bid versus placebo in 265 women with platinum-sensitive relapsed high-grade serous ovarian carcinomas who were in partial or complete response following their last platinum-containing regimen. *BRCA1/2* mutation status was not required. Median progression-free survival was significantly longer with olaparib than with placebo (8.4 vs. 4.8 months). Overall survival data were not mature, but a preliminary analysis showed no difference between the groups (29.7 months for olaparib versus 29.9 months for placebo). The most common toxicities were low-grade nausea, vomiting, fatigue, and anemia (532).

Yet another phase II trial randomized 162 women with platinum sensitive recurrent disease, again unselected for *BRCA1/2* mutation status, to carboplatin AUC6/paclitaxel 175 mg/m² chemotherapy for 6 cycles followed by no further therapy versus the combination of open label olaparib plus carboplatin AUC4/paclitaxel 175 mg/m² chemotherapy followed by olaparib maintenance. A lower carboplatin dose had to be used in the combination regimen because olaparib adds to hematologic toxicity. Results have been reported in abstract form. Response rates were similar for the 2 arms at 64% for olaparib and 58% for chemotherapy alone; progression-free survival was improved at 12.2 versus 9.6 months (533).

In summary, while olaparib clearly has single agent activity with what appears to be an acceptable toxicity profile, and has a compelling biologic mechanism, it has thus far not proved superior to standard therapy (pegylated liposomal doxorubicin) for women with recurrent disease and has not improved response rates when added to chemotherapy. It substantially prolongs progression-free survival when used as maintenance therapy, but has not improved overall survival. Definition of the role of PARP inhibitors in our armamentarium against ovarian cancer awaits results of further clinical trials.

Agents Targeting Angiogenesis

Bevacizumab, a monoclonal antibody targeting VEGF, is the most extensively tested antiangiogenic agent for ovarian cancer, and results of trials of bevacizumab in ovarian cancer are

discussed above (Table 24.14). Numerous other antiangiogenic agents are being evaluated in women with ovarian cancer, and many of them target different or multiple components of the angiogenic pathway or other pathways. Aflibercept (VEGF-TRAP) is a high-affinity soluble decoy receptor that comprises portions of the extracellular domains of both VEGFR-1 and VEGFR-2. Preliminary clinical trial reports have suggested some activity against platinum-resistant ovarian cancers. A phase 2 study randomizing ovarian cancer patients to aflibercept or placebo for the treatment of recurrent malignant ascites showed that aflibercept significantly prolonged time to first paracentesis (55 vs. 23 days) but caused a 10% gastrointestinal perforation rate, similar to that observed in heavily pretreated women receiving bevacizumab (558). Ramucirumab (IMC1121B), a monoclonal antibody to VEGFR2, produced a 5% PR rate (3 of 60) among a heavily pretreated group of patients: 75% had platinum resistant or refractory disease (534). AMG 386 is a peptide-Fc fusion protein that neutralizes the interaction between the Tie2 receptor and angiopoietin-1/2. A randomized phase II trial comparing weekly paclitaxel to weekly paclitaxel plus AMG 386 showed a statistically significant advantage in PFS to the combination, and an international phase III trial adding AMG386 to front-line therapy to ovarian cancer is underway. Toxicities reported include hypertension, peripheral edema, and hypokalemia (535).

A large number of small molecule inhibitors of VEGF receptor tyrosine kinase are in clinical development or have been approved for other cancers, particularly kidney cancer. Many of these also inhibit other kinases of relevance to angiogenic pathways, such as platelet-derived growth factor (PDGF) receptors or fibroblast growth factor (FGF) receptors. Single-agent phase 2 trials of sorafenib (536), sunitinib (537), cediranib (538), and pazopanib (539) have been reported. The best response rate reported was for pazopanib at 31%; however, this trial excluded women who did not have a complete response to primary chemotherapy, and included CA-125 responses. The response rate for women with measurable disease was only 18%. ENMD-2076 inhibits aurora kinase A as well as angiogenic kinases, and produced responses in 3 of 45 women with heavily pretreated platinum resistant disease (540). Cabozantinib (XL-184) inhibits RET, c-Met and c-kit as well as VEGFR2. A recent randomized discontinuation phase II trial of cabozantinib showed an overall response rate of 24%; it was 29% in patients with platinum sensitive ovarian cancer and 18% in patients with platinum resistant disease (541). Larger randomized trials with cediranib, nintedanib (also known as BIBF 1120) and pazopanib are underway or have been completed, and results are awaited.

Mechanisms of escape from antiangiogenic therapy continue to be studied. For example, IGF-1 activation has been described mechanism of adaptive escape during anti-VEGF therapy in ovarian cancer, which suggests that antiangiogenic therapy combined with IGF-1 blockade might be of interest (542).

Immunologic Therapies

It has long been known that immune therapies, such as Interleukin-2 (IL-2), have some activity in the treatment of ovarian cancer. In 2003 Zhang et al. made the observation that among patients in clinical complete remission the presence of intratumoral T cells was a strongly favorable prognostic factor (543). CD3⁺ tumor-infiltrating T cells were detected within tumor cell islets in 102 of 186 tumors (54.8%). The 5-year survival rate was 38% for patients whose tumors contained T cells compared to 4.5% for patients without tumor-infiltrating T cells. However, no immune therapy has yet been generally successful in the treatment of ovarian cancer.

Multiple large randomized trials have tested monoclonal antibodies targeting tumor-associated antigens, such as CA-125

and MUC-1, and these have been disappointing even in patients with the most favorable prognostic factors (optimal debulking, complete clinical response to chemotherapy) (544). Newer generations of antibodies linked to cytotoxic chemicals are emerging, and may be useful against ovarian cancer. There also remains substantial interest in vaccine-type therapies, which have used a variety of antigens, including MUC 1 carbohydrate epitope, p53 peptide, HER2/neu peptides, and the cancer-testis antigen NY-ESO-1, which are sometimes directly injected, sometimes loaded onto dendritic cells, and sometimes expressed in recombinant viral vectors. The GOG is currently conducting a randomized double-blind phase II vaccine trial in women with ovarian cancer in second or third complete remission. The agent is a polyvalent antigen-keyhole limpet hemocyanin (KLH) construct of numerous carbohydrate cell surface epitopes, which is administered with an immunological adjuvant.

Proof of principle that ovarian cancers can respond to immunologic approaches was seen in a large phase I trial of BMS-936559, an anti-programmed death ligand-1 (PDL-1) monoclonal antibody that potentiates immune responses and mediates antitumor activity in preclinical models. Seventeen patients with ovarian cancer were enrolled. One had a partial response, and 3 had stable disease lasting at least 24 weeks (545).

Other New Directions

The folate receptor is highly overexpressed in ovarian cancer, and a number of therapies have attempted to take advantage of this. Farletuzumab is an antifolate receptor antibody. A phase III randomized, double-blind, placebo-controlled study evaluating farletuzumab in combination with weekly paclitaxel in patients with platinum-resistant or refractory ovarian was closed to accrual after failure to meet predefined efficacy endpoints at interim analysis, but the phase III study evaluating this agent in combination with carboplatin and taxane in platinum-sensitive ovarian cancer in first relapse has not yet been reported (546). EC145 is a conjugate of folic acid and desacetylvinblastine that binds to the folate receptor with high affinity. A phase II trial suggested that this agent produced a significant improvement in

progression free survival when combined with PLD (21.7 weeks) compared to PLD alone (11.7 weeks) in patients with platinum-resistant ovarian cancer (547), and a phase III trial is ongoing.

As discussed above, high-grade serous cancer is characterized by near universal aberration in the *P53* tumor-suppressor gene. The *P53* gene is a cell cycle checkpoint regulator, and cells with *P53* mutations are more dependent on other cell checkpoint regulators, such as Wee-1. Inhibition of Wee-1 in *p53*-deficient tumors leads to reduced capacity for repair to damage to DNA, such as that induced by chemotherapy. MK-1777 is a Wee-1 tyrosine kinase inhibitor, and an ongoing randomized, placebo-controlled phase II study is evaluating paclitaxel and carboplatin with or without the Wee-1 tyrosine kinase inhibitor MK-1775 in women with *p53* mutation-positive platinum-sensitive recurrent ovarian cancer (546).

Aberrant DNA methylation is a frequent epigenetic event in ovarian cancer and represents an additional source of potential molecular markers. Four promoter methylation subtypes significantly associated with survival were identified in high-grade serous tumors by the Tumor Cancer Genome Atlas Project (530). Wei et al. investigated CpG island hypermethylation across stages III and intravenous ovarian tumors (548). Hierarchical clustering revealed 2 tumor groups with distinctly different methylation profiles. The duration of progression-free survival after chemotherapy was significantly shorter for patients whose tumors contained high levels of concurrent methylation compared to patients whose tumors had lower tumor methylation levels. Hypomethylating agents and histone deacetylase inhibitors are currently being studied in combination with standard chemotherapies with some interesting results. Matei et al. tested low-dose decitabine administered before carboplatin in 17 patients with heavily pretreated and platinum-resistant ovarian cancer. The regimen induced a 35% objective response rate and a progression-free survival of 10.2 months, with 9 patients (53%) free of progression at 6 months. Demethylation of *MLH1*, *RASSF1A*, *HOXA10*, and *HOXA11* in tumor biopsies after treatment positively correlated with PFS, suggesting that low-dose decitabine altered DNA methylation of genes, restoring sensitivity to carboplatin (549). A phase I/II randomized trial of carboplatin with or without SGI-110, a small molecule DNA hypomethylating agent, in patients with platinum-resistant disease is planned.

INTRODUCTION

Significant improvement in the management of ovarian germ cell tumors (OGCT) has been achieved during the past 3 decades. The development of more effective chemotherapy regimens is the leading cause for improved outcome in this rare group of patients. Other advancements in the field include the development of a more precise surgical staging system, improved radiographic imaging, more sophisticated pathology techniques, as well as improved supportive care and symptom control that has enabled safe delivery of treatment. A substantial majority of patients with OGCT are long-term survivors and suffer minimal morbidity from treatment. Fertility-sparing surgical procedures enable young women with OGCT to preserve their reproductive potential. These positive results in clinical outcome reflect a collaborative effort between different specialties (surgery, medical oncology, pathology, and radiology).

PATHOLOGY

The current World Health Organization (WHO) classification of OGCTs includes dysgerminoma, yolk sac tumor, embryonal carcinoma, polyembryoma, nongestational choriocarcinoma, mixed germ cell tumors, and teratomas (immature, mature, and monodermal types) (1). Primitive germ cell tumors account for 2% to 3% of all ovarian cancers and occur usually in young women. The peak age incidence for development of these tumors is the early twenties. The pathology of these neoplasms is discussed here in the same order as the listing in the current WHO classification.

Dysgerminoma

Dysgerminoma represents the most common ovarian malignant germ cell tumor (2). Most dysgerminomas are seen in patients with a normal karyotype, but it is the most frequent ovarian neoplasm in patients with gonadal dysgenesis. About 5% to 10% are associated with gonadoblastomas in sexually maldeveloped patients. Most dysgerminomas occur in normal females who usually present with abdominal enlargement, a mass, or pain due to torsion. About 10% of dysgerminomas are bilateral on gross examination and another 10% have microscopic involvement of the contralateral ovary. Association with gonadoblastoma increases the risk of bilateral involvement by dysgerminoma.

On gross examination, dysgerminomas are usually large, white to gray, fleshy lobulated masses that have no more than

very focal areas of hemorrhage or necrosis on cut section. Abundant hemorrhage, necrosis, or cystic areas in a well-fixed tumor should raise the question of a mixed germ cell tumor. Microscopically, dysgerminomas display nests and cords of primitive-appearing germ cells with clear to eosinophilic cytoplasm and prominent cytoplasmic borders (Fig. 25.1). Nuclei are enlarged but they are not pleomorphic. Mitoses may be numerous, and the number of mitotic figures does not have any therapeutic or prognostic significance. Nests of tumor cells are separated by fibrous trabeculae that contain lymphocytes and, sometimes, granulomas. Syncytiotrophoblast cells are present in about 3% of dysgerminomas.

Dysgerminomas contain cytoplasmic glycogen that can be demonstrated with periodic acid Schiff (PAS) stain. These tumors display diffuse staining for placenta-like alkaline phosphatase (PLAP), usually with accentuation of the cytoplasmic membrane. Positive staining for c-kit (3) and the nuclear transcription factor OCT 3/4 (4) are helpful in confirming this diagnosis, dysgerminoma being the only OGCT that displays c-kit staining (5). Approximately one-third of dysgerminomas harbor c-kit amplifications or activating mutations, and these molecular alterations correlate with advanced stage (6). Both dysgerminoma and embryonal carcinoma stain for OCT 3/4. In contrast to embryonal carcinoma, dysgerminoma does not stain for CD30. Syncytiotrophoblast cells present in dysgerminomas display human chorionic gonadotropin (HCG) staining. In contrast to choriocarcinoma, the syncytiotrophoblast cells in dysgerminomas are not admixed with cytotrophoblast cells. Dysgerminomas do not produce alpha-fetoprotein (AFP), a finding that may be helpful in distinguishing them from the solid variant of yolk sac tumor. Optimal and prompt fixation of the surgical specimen facilitates the correct diagnosis. Poor fixation can result in artifacts that mimic embryonal carcinoma and yolk sac tumor histology.

Yolk Sac Tumor

Yolk sac tumor (endodermal sinus tumor) is the second most common OGCT, accounting for 22% of cases studied at the Armed Forces Institute of Pathology (AFIP) (2,7). These tumors grow very rapidly, often becoming clinically evident in less than 1 month.

Ovarian yolk sac tumors are typically large and unilateral, although metastasis to the opposite ovary may occur. These tumors have a smooth external surface unless rupture or invasion into surrounding structures has occurred. On cut section, these neoplasms are tan to gray, with abundant hemorrhage and necrosis. They may be partially solid, but they usually contain cysts that vary in size from a few millimeters to several centimeters in diameter. The cut surface appears mucoid, slimy,

FIGURE 25.1. Dysgerminoma. This neoplasm has nests of cells with clear cytoplasm and enlarged hyperchromatic nuclei. Fibrous septae containing lymphocytes separate nests of tumor.

or gelatinous. Yolk sac tumor (7) display many different histologic patterns (8). The most common microscopic pattern in primary ovarian tumors is the reticular or microcystic pattern (Fig. 25.2). The tumor has a mesh-like pattern and it displays a network of flattened or cuboidal epithelial cells with varying degrees of atypia. The endodermal sinus (festoon) pattern contains Schiller-Duval bodies (Fig. 25.3) that have a central capillary surrounded by connective tissue and a peripheral layer of columnar cells. These structures are situated in cavities lined by yolk sac tumor cells. When present, Schiller-Duval bodies are diagnostic of yolk sac tumor. Other less common variants of yolk sac tumor include hepatoid, polyvesicular vitelline, enteric, endometrioid, solid, parietal, and mesenchymal patterns. Most patterns of yolk sac tumor may contain eosinophilic hyaline globules that are PAS positive and diastase resistant. These globules may be seen in non-germ cell tumors and they are not specific for yolk sac tumor. They do not contain AFP. Yolk sac tumors generally display cytoplasmic staining for cytokeratin and AFP, although the parietal pattern of yolk sac tumor typically does not contain AFP. Therefore, serum AFP is a useful marker for yolk sac tumor, although a negative serum AFP

FIGURE 25.2. Reticular pattern of yolk sac tumor. There is a mesh-like arrangement of cuboidal tumor cells.

FIGURE 25.3. Schiller-Duval bodies, papillary structures with central blood vessels, are seen in the endodermal sinus pattern of yolk sac tumor.

does not exclude the disease. Chemotherapy has resulted in the appearance of AFP-negative parietal yolk sac tumor after eradication of AFP-positive patterns of the tumor (9). Enteric glands in yolk sac tumor may be carcinoembryonic antigen (CEA)-positive. Some types of yolk sac tumor need to be differentiated from endometrioid and clear cell tumors of the ovary. Germ cell tumors usually occur in younger patients than epithelial ovarian tumors, but the lack of staining for cytokeratin 7 and epithelial membrane antigen supports a diagnosis of yolk sac tumor (10) in controversial neoplasms.

Embryonal Carcinoma

Embryonal carcinoma is rarely seen in the ovary, in contrast to its frequent occurrence in the testis. Only 14 cases were identified during a period of 30 years at the AFIP (11), and there have been no recent large series of these tumors. Embryonal carcinoma of the ovary is usually associated with yolk sac tumor in mixed germ cell tumors. On gross examination, embryonal carcinoma characteristically displays areas of hemorrhage and necrosis. Microscopically, this tumor is composed of very crowded cells that display overlapping nuclei in paraffin sections. The nuclei are very pleomorphic and they contain large, prominent nucleoli. The mitotic rate is high in these tumors. Glandular, solid, and papillary patterns may be seen. Vascular invasion is common. Embryonal carcinoma stains positively for PLAP, pan-cytokeratin (AE1/AE3 and CAM 5.2), CD30, and OCT3/4. In contrast to seminoma, embryonal carcinoma does not display c-kit staining. Some embryonal carcinomas display focal AFP positivity that may represent partial transformation to yolk sac tumor. Syncytiotrophoblast cells may be present. They produce hCG, but they are not accompanied by admixed cytotrophoblast cells unless choriocarcinoma is also present.

Polyembryoma

Polyembryoma is a very rare malignant ovarian tumor (2). In the few cases reported, the embryoid bodies characteristic of this germ cell tumor have coexisted with other germ cell tumor types. The microscopic appearance of embryoid bodies (12), with an embryonic disc separating a yolk sac and an amniotic cavity, may actually be due to an admixture of yolk sac tumor and embryonal carcinoma.

FIGURE 25.4. Choriocarcinoma. This ovarian neoplasm is extremely hemorrhagic.

Choriocarcinoma

Primary nongestational ovarian choriocarcinoma is rare (13). It is most often seen as a component of mixed germ cell tumors of the ovary (14,15). Choriocarcinomas display abundant hemorrhage and necrosis on gross examination (Fig. 25.4). Microscopically, these neoplasms show a plexiform pattern composed of an admixture of syncytiotrophoblast and cytotrophoblast cells (Fig. 25.5). Syncytiotrophoblastic giant cells have abundant eosinophilic to amphophilic cytoplasm that contains multiple atypical, hyperchromatic nuclei. Cytotrophoblast cells are round and often have well-defined cell borders, clear to lightly eosinophilic cytoplasm, and single, atypical nuclei. Numerous mitoses are present. Choriocarcinoma spreads by blood vessel invasion that is easy to identify in these tumors. Cytotrophoblast cells do not produce hCG. Syncytiotrophoblast cells are formed from cytotrophoblast cells, and syncytiotrophoblast does produce hCG. Choriocarcinoma may also stain for cytokeratins, epithelial membrane antigen, and carcinoembryonic antigen. Nongestational choriocarcinoma must be distinguished

FIGURE 25.5. Choriocarcinoma. Syncytiotrophoblastic cells have dark cytoplasm and multiple atypical nuclei. Cytotrophoblastic cells have lighter cytoplasm and single atypical nuclei. Both cell types are admixed in choriocarcinoma. Areas of hemorrhage and necrosis are common.

from gestational choriocarcinoma because the former has a worse prognosis and requires more aggressive therapy. Identification of paternal genetic material indicates that the tumor is of gestational origin (16).

Mixed Germ Cell Tumors

Mixed germ cell tumors of the ovary contain 2 or more different types of germ cell neoplasm, either intimately admixed or as separate foci within the tumor (14,15). They are much less common in the ovary than in the testis. They accounted for only 8% of malignant ovarian germ cell tumors accessioned at the AFIP over a period of 30 years (14).

Malignant mixed germ cell tumors are large, unilateral neoplasms, but the gross appearance on the cut surface depends on the particular types of germ cell tumor present. The most common germ cell tumor element in the AFIP series was dysgerminoma (80%), followed by yolk sac tumor (70%), teratoma (53%), choriocarcinoma (20%), and embryonal carcinoma (13%) (14). The most frequent combination has been dysgerminoma and yolk sac tumor. Syncytiotrophoblast may occur either as a component of choriocarcinoma or as isolated cells in other germ cell tumor elements. The diagnosis and prognosis of malignant mixed germ cell tumors depend on adequate tumor sampling to detect small areas of different types of germ cell tumor. Thorough sampling is essential because the types of tumor identified may affect therapy and prognosis.

Teratomas

Teratomas are germ cell tumors that contain tissue derived from 2 or 3 embryonic layers. Teratomas are subclassified according to whether the tumor elements represent mature or immature tissue types. In addition, monodermal and highly specialized teratomas are composed of a predominance of one tissue type such as thyroid tissue (struma ovarii). This discussion of the pathology of ovarian tumors will address predominantly mature and immature teratomas in adult women. In contrast to other ovarian germ cell tumor types, ovarian teratomas do not contain 12p amplification (17,18). Ovarian teratomas apparently arise by parthenogenesis.

Most teratomas are mature cystic teratomas that contain differentiated tissue components such as skin, cartilage, glia, glandular elements, and bone. Any tissue type present in adults may be represented in teratomas. The widest variety of tissue types is characteristically identified in a nodule in the wall of the cystic neoplasms. Mature cystic teratomas represent benign neoplasms unless they contain a somatic malignancy such as squamous carcinoma, papillary thyroid carcinoma, or other non-germ cell tumors arising in differentiated elements of the teratoma.

Immature teratomas in adult women, in contrast to mature cystic teratomas, are uncommon tumors. They represent about 3% of all ovarian teratomas, but immature teratomas are the third most common form of malignant ovarian germ cell tumors. Very limited amounts of immature tissue occurring in mature cystic teratomas do not seem to alter the prognosis of those tumors (19), but immature tissue in solid teratomas represents a malignant tumor that can disseminate and metastasize.

Most immature ovarian teratomas are unilateral neoplasms, although they can metastasize to the opposite ovary and they can also be associated with mature teratoma in the opposite ovary. Immature teratomas are predominantly solid tumors, but they may contain some cystic areas. The cut surface of immature teratomas is soft and fleshy or encephaloid in appearance (Fig. 25.6). Areas of hemorrhage and necrosis are common. Microscopically, these tumors contain a variety of mature and immature tissue components. The immature elements almost

FIGURE 25.6. Ovarian immature teratoma. The neoplasm is predominantly solid and has a soft, encephaloid appearance.

always consist of immature neural tissue in the form of small round blue cells focally organized into rosettes and tubules (Fig. 25.7). There is a correlation between disease prognosis and the degree of immaturity in the teratoma. The 3-tiered grading system is still the one most often used (20). Grade 1 neoplasms display some immaturity, but the immature neural tissue does not exceed, in aggregate, the area of one low-power field (40X) in any slide. Grade 2 teratomas contain more immaturity, but immature neural tissue occupies no more than an area equal to 3 low-power fields in any slide. Grade 3 neoplasms contain immature neural tissue that occupies an area greater than 3 low-power fields in at least one slide (21). Mature tissue is easily identified in grade 1 tumors. It is present to a lesser extent in grade 2 neoplasms and may be absent altogether in grade 3 immature teratomas. The amount of mitotic activity and immature neural tissue with rosettes and tubules also increases with increasing tumor grade. Some authors prefer classifying immature teratomas as either low (grade 1) or high (grades 2 and 3) grade teratomas. In patients whose neoplasm has disseminated beyond the ovary, the grade of the tumor metastasis is important in predicting survival and determining treatment. Occasionally, patients may have peritoneal implants that contain only mature

FIGURE 25.7. Ovarian immature teratoma. Immature neural tissue forms tubules.

tissue, but these mature glial implants may represent host tissue and not actual tumor implants (22). It is extremely important to sample peritoneal disease thoroughly in order to identify foci of immature teratoma.

A rare, but distinct entity deserves mention. The **poorly differentiated small cell carcinoma of the ovary**, classically associated with hypercalcemia (23) may have germ cell origin, as suggested by immunostaining for α -1-antitrypsin, presence of PAS-positive intracellular globules, presence of foci of intercellular basement membrane material, and focal laminin immunoreactivity (24). Microscopically, the small cell carcinoma of the ovary has similar features to that of the lung. Neuroendocrine differentiation is present with typical growth pattern, evidence of secretory granules, and expression of neuroendocrine markers; synaptophysin and chromogranin (25). These tumors occur usually in young women and are invariably associated with a dismal prognosis (26,27). Rapidly enlarging abdominal or pelvic mass is a common manifestation. Hypercalcemia is present in two-thirds of cases and small cell carcinoma is the most common cause of ovarian tumor-associated hypercalcemia. Because of its aggressive course, some women have symptoms of overt metastatic disease at presentation. Treatment with germ cell type chemotherapy regimen is probably justified, although data are scant and inconclusive, given the rarity of such tumors.

Biologically, ovarian germ cell tumors, like testis cancer, are derived from primordial germ cells, which undergo defective meiosis. Karyotypic abnormalities are common and include aneuploidy or chromosomal rearrangements. In contrast, benign teratomas have a normal karyotype. One report notes chromosomal abnormalities in 7% of mature teratomas (28,29). Analysis of centromeric heteromorphism suggests that 65% to 70% of benign teratomas result from a post-meiosis I type error (homozygotes), while the remaining 30% to 35% are caused by defective meiosis I, as demonstrated by heterozygosity of centromeric markers (28). Among malignant ovarian germ cell tumors, aneuploidy and chromosomal translocations or truncations similar to those encountered in testicular carcinoma have been widely reported (30,31). The presence of an isochromosome 12p (i12p) has been noted in ovarian tumors (32), albeit less commonly than in testis cancer. Other chromosomal aberrations such as loss or gain in chromosomes 1, 11, 12, 16, and X can be identified (33). The association between dysgerminoma and dysgenetic gonads (34) is well recognized and should be managed accordingly, as will be discussed.

Clinical Features

Malignant germ cell tumors of the ovary occur mainly in girls and young women.

In the University of Texas M.D. Anderson Cancer Center (UTMDACC) series, the age of the patients ranged from 6 to 40 years, with a median age of 16 to 20 years, depending upon histological type (35). There are ethnic and racial differences in the incidence of germ cell tumors, as shown in an analysis based on the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database, with increased incidence of OGCTs among pediatric Black females compared to Black males and among Hispanic girls aged 10 to 19 years, as compared to non-Hispanics (36). Interestingly, a case-cohort study from the Children Oncology Group, including 274 cases (195 OGCTs and 79 testicular cancers), showed that a family history of cancer was inversely correlated with the risk of developing germ cell tumors (37).

Signs and symptoms in these patients are rather consistent. Abdominal pain associated with a palpable pelvic-abdominal mass is present in approximately 85% of patients (15,38,39). Ten percent of patients present with acute abdominal pain,

usually caused by rupture, hemorrhage, or ovarian torsion. This finding is somewhat more common in patients with endodermal sinus tumor or mixed germ cell tumors and is frequently misdiagnosed as acute appendicitis. Less common signs and symptoms include abdominal distention (35%), fever (10%), and vaginal bleeding (10%). A few patients exhibit isosexual precocity, presumably due to hCG production by tumor cells.

In a small percentage of cases, ovarian germ cell tumors occur during pregnancy or in the immediate postpartum period (38). In the series reported by Gordon, 20 of 158 patients with dysgerminoma were diagnosed during pregnancy or after delivery (40). Nondysgerminomatous ovarian tumors occur less frequently during pregnancy, but rare cases have been reported (41–44). Marked increase in AFP heralds the presence of a germ cell tumor with yolk sac component. By and large, patients with ovarian tumors diagnosed during pregnancy can be treated successfully, without compromising the health of the fetus. Surgical resection of tumors and chemotherapy have been performed safely in mid and third trimesters. However, rapid disease progression and/or pregnancy termination/miscarriage have been recorded, especially for nondysgerminomatous tumors (45).

Many germ cell tumors possess the unique property of producing biologic markers that are detectable in serum. The development of specific and sensitive radioimmunoassay techniques to measure hCG and AFP led to dramatic improvements in patient monitoring. Serial measurements of serum markers aid the diagnosis and, more importantly, are useful for monitoring response to treatment and detection of subclinical recurrences. Table 25.1 illustrates typical findings in the sera of patients with various tumor histologic types. Endodermal sinus tumor and choriocarcinoma are prototypes for AFP and hCG production, respectively. Embryonal carcinoma can secrete both hCG and AFP, but most commonly produces hCG. Mixed tumors may produce either, both, or none of the markers, depending on the type and quantity of elements present. Dysgerminoma is commonly devoid of hormonal production, although a small percentage of tumors produces low levels of hCG, if multinucleated syncytiotrophoblastic giant cells are present. The presence of an elevated level of AFP or high level of hCG (>100 Units/mL) denotes the presence of tumor elements other than dysgerminoma. Therapy should be adjusted accordingly (see below). Although immature teratomas are associated with negative markers, a few tumors can produce AFP. A third tumor marker is lactic dehydrogenase (LDH), which is frequently elevated in patients with dysgerminoma or other germ cell tumors. Unfortunately, it is less specific than hCG or AFP, which limits its usefulness. CA-125 also can be nonspecifically elevated in patients with ovarian germ cell tumors (46). Age over 45 years, stage

greater than I, and yolk sac tumor histology have been identified as prognostic factors that affect survival (47).

SURGERY

Operative Findings

Malignant germ cell tumors of the ovary tend to be quite large. In the UTMDACC series, these tumors ranged in size from 7 to 40 cm, with a median size of 16 cm (15). Predominance of right-sided over left-sided involvement was noted. Bilaterality of tumor involvement (especially true stage IB disease) is exceedingly rare, except for dysgerminoma. Bilateral involvement occurs in 10% to 15% of dysgerminoma patients (40,48–51). For nondysgerminomatous tumors, bilateral involvement signifies either advanced disease with metastatic spread to the contralateral ovary or the presence of a mixed germ cell tumor with prominent dysgerminoma component.

Ascites may be noted in approximately 20% of cases. Rupture of tumors, either preoperatively or intraoperatively, can occur in approximately 20% of cases. Torsion of the ovarian pedicle was documented in 5% of patients in the UTMDACC series.

Benign cystic teratoma is associated with malignant germ cell tumors in 5% to 10% of cases. These coexistent teratomas may occur in the ipsilateral ovary, in the contralateral ovary, or bilaterally. Likewise, a preexisting gonadoblastoma may be noted in association with dysgerminoma and dysgenetic gonads related to a 46,XY karyotype (34,52–54).

Malignant germ cell tumors generally spread in 1 of 2 ways: along the peritoneal surface or through lymphatic dissemination. Although the relative frequency of these 2 principal mechanisms is difficult to discern, it is generally accepted that these neoplasms more commonly metastasize to lymph nodes than epithelial tumors. The high prevalence of inadequate staging procedures makes the true incidence of lymph node involvement uncertain. It is our impression that although still uncommon, malignant germ cell tumors have a somewhat greater predilection than epithelial tumors to metastasize hematogenously to parenchyma of liver or lung. The stage distribution is also very different from that of epithelial tumors. In most large series, approximately 60% to 70% of tumors will be stage I (40). The next most common stage is III, accounting for 25% to 30% of tumors. Stages II and IV are relatively uncommon.

Extent of Primary Surgery

The initial treatment approach for a patient suspected of having a malignant ovarian germ cell tumor is surgery, both for diagnosis and for therapy. After an adequate vertical midline incision, a thorough determination of the disease extent by inspection and palpation should be made. If the disease is confined to one or both ovaries, it is imperative that proper staging biopsies be performed (see below).

The type of primary operative procedure depends upon the surgical findings. Because many of these patients are young women, for whom preservation of fertility is a priority, minimizing the surgical resection while ensuring removal of tumor bulk must be thoughtfully balanced. As noted previously, bilateral ovarian involvement is rare, except for the case of pure dysgerminoma. Bilateral involvement may be found in cases of advanced disease (stages II–IV), in which there is metastasis from one ovary to the opposite gonad, or in cases of mixed germ cell tumors with dysgerminoma component. Therefore, fertility-sparing unilateral salpingo-oophorectomy with preservation of the contralateral ovary and of the uterus can be performed in

Table 25.1 Serum Tumor Markers in Malignant Germ Cell Tumors of the Ovary

Histology	AFP	hCG
Dysgerminoma	–	±
Endodermal sinus tumor	+	–
Immature teratoma	±	–
Mixed germ cell tumor	±	±
Choriocarcinoma	–	+
Embryonal carcinoma	±	+
Polyembryoma	±	+

most patients (55–57). If the contralateral ovary appears grossly normal on careful inspection, it should be left undisturbed. However, in the case of pure dysgerminoma, biopsy may be considered, because occult or microscopic tumor involvement occurs in a small percentage of patients. Unnecessary biopsy, however, may result in future infertility due to peritoneal adhesions or ovarian failure. If the contralateral ovary appears abnormally enlarged, a biopsy or ovarian cystectomy should be performed. If frozen examination reveals a dysgenetic gonad, or if there are clinical indications suggesting a hermaphrodite phenotype, then bilateral salpingo-oophorectomy is indicated. However, it is difficult to establish this diagnosis on frozen section. This determination should preferably be made by determining a normal female karyotype preoperatively. If benign cystic teratoma is found in the contralateral ovary, an event that can occur in 5% to 10% of patients, then ovarian cystectomy with preservation of remaining normal ovarian tissue is recommended.

An important problem, albeit rare, is bilateral gonadal involvement in a patient who desires to preserve fertility and who is a candidate for postoperative chemotherapy. There are no data regarding the ability of chemotherapy to eradicate a primary ovarian tumor. In testis cancer, there are presumptive data suggesting that tumor may persist after chemotherapy in the gonad and that the testis may be a drug sanctuary. In exceptional situations, it may be reasonable to preserve an involved ovary in a patient who will be receiving chemotherapy. However, it is conceivable that ovarian preservation could increase the risk for recurrence in these selected cases. The decision to preserve an involved ovary is difficult and must be made carefully considering patient's wishes.

The advent of *in vitro* fertilization technology also has an impact on operative management (58). Convention has dictated that if a bilateral salpingo-oophorectomy is necessary, a hysterectomy should also be performed. However, with current assisted reproduction technologies (ART) involving donor oocyte and hormonal support, a woman without ovaries could potentially sustain a normal intrauterine pregnancy. Similarly, if the uterus and one ovary are resected because of tumor involvement, current techniques provide the opportunity for oocyte retrieval from the remaining ovary, *in vitro* fertilization with sperm from her male partner, and embryo implantation into a surrogate's uterus. As the field of ARTs is evolving, traditional guidelines concerning surgical treatment in young patients with gynecologic tumors have to be thoughtfully adapted to individual circumstances.

Surgical Staging

Surgical staging information is essential for determining extent of disease, providing prognostic information, and guiding postoperative management. A meticulous approach is important for every patient, but is of critical importance for those patients with early clinical disease to detect the presence of occult or microscopic metastases. Staging of ovarian germ cell tumors follows the same principles applicable to epithelial ovarian tumors, as described by the International Federation of Gynecologists and Obstetricians (FIGO); see Table 25.2. Proper staging procedures consist of the following:

1. Although a transverse incision is cosmetically superior, a vertical midline incision is usually necessary for adequate exposure, appropriate staging biopsies, and resection of large pelvic tumors or metastatic disease in the upper abdomen.
2. Ascites, if present, should be evacuated and submitted for cytologic analysis. If no peritoneal fluid is noted, cytologic washings of the pelvis and bilateral paracolic gutters should be performed prior to manipulation of the intraperitoneal contents.

Table 25.2 FIGO Staging of Ovarian Germ Cell Tumors

Stage	Description
I	Tumor limited to ovaries.
IA	Tumor limited to one ovary, no ascites, intact capsule.
IB	Tumor limited to both ovaries, no ascites, intact capsule.
IC	Tumor either stage IA or IB, but with ascites present containing malignant cells or with ovarian capsule involvement or rupture or with positive peritoneal washings.
II	Tumor involving one or both ovaries with extension to the pelvis.
IIA	Extension to uterus or tubes.
IIB	Involvement of both ovaries with pelvic extension.
IIC	Tumor either stage IIA or IIB, but with ascites present containing malignant cells or with ovarian capsule involvement or rupture or with positive peritoneal washings.
III	Tumor involving one or both ovaries with tumor implants outside the pelvis or with positive retroperitoneal or inguinal lymph nodes. Superficial liver metastases qualify as stage III.
IIIA	Tumor limited to the pelvis with negative nodes but with microscopic seeding of the abdominal peritoneal surface.
IIIB	Negative nodes, tumor implants in the abdominal cavity <2 cm.
IIIC	Positive nodes or tumor implants in the abdominal cavity >2 cm.
IV	Distant metastases present.

3. The entire peritoneal cavity and its structures should be carefully inspected and palpated in a methodical manner. We generally prefer to start with the subphrenic spaces and move caudad toward the pelvis. The subdiaphragmatic areas, omentum, colon, all peritoneal surfaces, the entire retroperitoneum, and small intestinal serosa and mesentery should be checked. If any suspicious areas are noted, they should be submitted for biopsy or excised.
4. Next, the primary ovarian tumor and pelvis should be examined. Both ovaries should carefully be assessed for size, presence of obvious tumor involvement, capsular rupture, external excrescences, or adherence to surrounding structures.
5. If disease seems to be limited, that is, confined to the ovary or localized to the pelvis, then random staging biopsies of structures at risk should be performed. These sites should include the omentum (with generous biopsies from multiple areas) and the peritoneal surfaces of the following sites: bilateral paracolic gutters, cul-de-sac, lateral pelvic walls, vesicouterine reflection, and subdiaphragmatic areas. Any adhesions should also be generously sampled.
6. The paraaortic and bilateral pelvic lymph node-bearing areas should be carefully palpated. Any suspicious nodes should be excised or sampled. If no suspicious areas are detected, these areas should be sampled. There is no evidence that a complete paraaortic and/or pelvic lymphadenectomy is advantageous.
7. If obvious gross metastatic disease is present, it should be excised if feasible, or at least sampled to document disease extent. The concept of cytoreductive surgery is discussed below.

The gynecologic literature is replete with examples of inadequate surgical staging. The assumption that surgical staging in the 1990s is superior to that of several years ago may be erroneous. Most patients still undergo initial surgery in community hospitals and are inadequately staged. Upon referral of such a patient to a university or tertiary care center, the oncologist is faced with the dilemma of inadequate staging information. In such cases, postoperative studies including computed tomography of the abdomen are recommended. If histopathologic and limited anatomic information from the first surgery clearly indicates the use of systemic chemotherapy, it is generally inadvisable to consider re-exploration solely for the purpose of precise staging information. Reoperation to complete comprehensive staging may be appropriate under clinical circumstances where careful surveillance observation after complete staging is a sensible alternative to chemotherapy.

Cytoreductive Surgery

If widely spread tumor is encountered at initial surgery, it is recommended that the same principles concerning cytoreductive surgery applied in the surgical management of advanced epithelial ovarian cancer be followed. Specifically, as much tumor as is technically feasible and safe should be resected. However, because of their rarity, there is scant information in the literature on the impact of cytoreductive surgery of malignant germ cell tumors.

In a study of the Gynecologic Oncology Group (GOG), Slayton et al. found that 15 of 54 (28%) patients with completely resected disease at primary surgery failed chemotherapy with a combination of vincristine, dactinomycin, and cyclophosphamide (VAC), as opposed to 15 of 22 (68%) patients with incompletely resected disease treated with the same regimen (59). Furthermore, a higher percentage of patients with bulky postoperative residual disease (82%) failed chemotherapy compared to those with minimal residual disease (55%). In a subsequent GOG study reported by Williams, patients received the combination regimen of cisplatin, vinblastine, and bleomycin (PVB). In this study, patients with nondysgerminomatous tumors and clinically nonmeasurable disease after surgery, had a greater likelihood of remaining progression-free than those with measurable disease (65% vs. 34%) (60). In addition, patients who had been surgically debulked to optimal disease had an outcome intermediate between patients with suboptimal disease and those with optimal disease without debulking.

Even with epithelial tumors, the relative influence of tumor biology, surgical skill, and aggressiveness remains uncertain. Germ cell tumors, especially dysgerminomas, are generally much more chemosensitive than epithelial ovarian tumors. Therefore, aggressive resection of metastatic disease in these cases, especially resection of bulky retroperitoneal nodes, is questionable. The surgeon must exercise thoughtful and mature intraoperative judgment when encountering such situations, carefully weighing the risks of cytoreductive maneuvers in the setting of chemosensitive tumors. There is no substitute for surgical experience and a clear understanding of the biological behavior of these neoplasms. Even in the face of extensive metastatic disease, it is possible to perform a fertility-sparing procedure with preservation of a normal contralateral ovary.

The value of secondary cytoreductive surgery in the management of malignant ovarian germ cell tumors is even less clear than that of primary cytoreductive surgery. Although secondary cytoreduction is of questionable benefit for patients with refractory epithelial ovarian cancer (61,62), germ cell tumors are relatively more chemosensitive than epithelial tumors and more likely to respond to second-line therapy. Therefore, if a patient has an isolated focus of persistent tumor after first-line chemotherapy in an area such as the lung, liver, retroperitoneum, or

brain, then surgical extirpation should be considered before changing chemotherapy regimens. Although this clinical situation is extremely rare, it has been observed in other situations involving chemosensitive tumors, such as gestational trophoblastic disease and testicular cancer.

Unlike testicular cancer, the finding of a residual mass after completion of chemotherapy is less common in patients with ovarian germ cell tumors because these women are likely to have considerable tumor debulking at the time of the diagnostic surgical procedure and thus enter chemotherapy with significantly less tumor burden. At completion of chemotherapy, men with nonseminomatous tumors or seminoma may have persistent mature teratoma or desmoplastic fibrosis. In patients with bulky dysgerminoma, residual masses after chemotherapy are very likely to represent desmoplastic fibrosis. Although a number of patients with pure ovarian immature teratomas or mixed germ cell tumors have persistent mature teratoma at the completion of chemotherapy, as documented by second-look laparotomy (63), the majority are left with multiple small peritoneal implants rather than with a dominant mass. However, it is now recognized that occasional patients who have received chemotherapy for immature teratoma or mixed germ cell tumor containing teratoma will have bulky residual teratoma after chemotherapy. The natural history or biologic implications of this finding are not clear. In testicular cancer, patients with bulky residual teratoma may experience slow progression of tumor (64) or may develop overtly malignant tumors over time (65–68). There are similar anecdotal reports of progressive mature teratoma in ovarian germ cell tumor patients after chemotherapy (69–71). Considering this information, it seems appropriate to resect persistent masses in patients with negative markers after chemotherapy for germ cell tumors containing immature teratoma. If viable neoplasm is found, additional chemotherapy should be considered. However, if only mature teratoma is resected, observation is generally recommended.

Second-Look Laparotomy

Since 1960, second-look laparotomy was included in the routine management of patients with epithelial ovarian cancer to assess disease status after a fixed interval of chemotherapy. It was only natural that such an approach would be extrapolated to the management of patients with malignant ovarian germ cell tumors. In a review of the experience with second-look laparotomy at UTMDACC, findings were negative in 52 of 53 patients (72). The one patient with positive findings at second-look laparotomy had an elevated AFP level prior to surgery, which accurately predicted residual disease. This patient received subsequent chemotherapy with PVB, entering prolonged remission. Of the patients with negative findings, one woman relapsed 9 months after the negative second look surgery and subsequently died. Thirteen patients in this series had biopsy-proven evidence of residual mature teratoma (so-called “chemotherapeutic retroconversion”) at second-look laparotomy; treatment was discontinued in all patients and none developed recurrence. Thus, in this series, second-look surgery did not add prognostic information or alter the therapeutic management of patients. The role of second-look surgery is further obscured in the setting of advancement in imaging techniques (CT scanning, PET, and MRI) and in an era where tumor marker measurements are part of routine care of patients with germ cell tumors.

The GOG experience with second-look laparotomy in ovarian germ cell tumors has been reviewed (63). One hundred seventeen patients enrolled prospectively on 1 of 3 GOG protocols using cisplatin-based chemotherapy after initial surgical staging and cytoreduction (GOG protocols #45, 78, and 90) underwent

second-look surgical procedures. Of these, 45 surgical procedures were performed in patients who received 3 courses of cisplatin, etoposide, and bleomycin (BEP) after complete tumor resection. In this subgroup, 38 patients had negative findings, 2 patients had immature teratoma, and 5 patients had mature teratoma. One of the patients with residual immature teratoma received further chemotherapy and one did not. Both these and the rest of patients were disease-free. One patient with negative second-look surgery findings subsequently relapsed and succumbed to disease. Hence, in the subgroup of patients with completely resected primary ovarian germ cell tumors, the benefit of second-look surgery is nil. In contrast, 72 patients in this series treated with similar chemotherapy had advanced incompletely resected tumor before beginning adjuvant treatment. In this subgroup, 48 patients did not have teratoma elements in their primary tumor. At second-look surgery, 45 patients had no residual tumor and 3 patients displayed persistent endodermal sinus tumor or embryonal carcinoma. All 3 of the latter patients died despite further treatment. Five patients with negative second laparotomies recurred, of which only one was salvaged with chemotherapy. Thus, the value of second look surgery in patients with incompletely resected germ cell tumors, not containing teratoma is arguably minimal. However, in the subgroup of patients with incompletely resected tumors containing teratoma elements (total of 24 patients), second-look surgery had an impact on subsequent management. Of these patients, 16 were found to have mature teratoma at second look, which was bulky or progressive in 7 cases. Four additional patients were found to have residual immature teratoma. Fourteen of the total 16 patients with teratoma and 6 of the 7 women with bulky residual tumor remained disease free after surgical resection. Therefore, while second-look laparotomy is not necessary in patients with tumor completely resected primarily or in those patients with initially incompletely resected tumor not containing teratoma, clinical benefit can be derived in those patients with incompletely resected **primary** tumor that contains elements of teratoma (see Table 25.3).

Advances in imaging technology, including the advent of positron emission tomography (PET scanning) may further obviate the need for surgical re-exploration. While PET scan is sensitive for detecting active (malignant) tumor, its usefulness in evaluating residual mature teratoma is more limited (73–76). A positive PET scan in the setting of a residual mass after treatment is

highly indicative of viable tumor and when used in conjunction with traditional radiographic techniques (CT scan, MRI) and tumor marker determinations, can predict relapses with accuracy (77). A recent series demonstrates that in patients with residual masses after treatment for seminoma, a positive PET scan is strong evidence that the residual mass contains persistent tumor. In contrast, if the PET scan is negative, residual masses are unlikely to contain active tumor. The specificity of the PET scan in this situation was 100%, the sensitivity was 80%, and the positive and negative predictive values were 100% and 95%, respectively (78). Although studies using PET scanning in OGCT are scant (79,80), the concepts are very similar and can be extrapolated from the testis cancer literature.

CHEMOTHERAPY FOR OVARIAN GERM CELL TUMORS

Chemotherapy: From VAC to PEB

One of the great triumphs of cancer treatment in the 1970s and 1980s has been the development of effective chemotherapy for testicular cancer (81,82). The lessons learned from prospective, randomized trials in testicular cancer subsequently have been applied to OGCTs. Presently, the overwhelming majority of patients with ovarian germ cell tumors survive their disease with the judicious use of surgery and cisplatin-based combination chemotherapy. There are many similarities, but a few important differences between testicular cancer and OGCTs.

Historically, the first regimens used successfully for women with OGCTs were VAC (vincristine, dactinomycin, and cyclophosphamide) or VAC-type regimens. Such treatment had curative potential, especially in early-stage disease. However, among patients with advanced disease, the number of long-term survivors after VAC therapy remained under 50%. In the series reported from UTMDACC, although 86% of patients with stage I tumors were cured with VAC, the efficacy of the regimen was significantly lower for patients with advanced disease (35). Only 57% of stage II patients and 50% of patients with stage III achieved long-term control. The 2 patients with stage IV tumors in this series succumbed to disease. Similarly, in a GOG study, only 7 out of 22 patients with incompletely resected OGCTs achieved long-term disease control after VAC, as compared to 39 of 54 patients with completely resected tumors (83). In that report, 11 of 15 patients with stage III and both patients with stage IV disease progressed within 12 months. These data suggest that VAC chemotherapy was insufficient for the treatment of advanced stage and/or incompletely resected OGCTs.

Because of the experience gained from the treatment of testicular germ cell tumors demonstrating the superiority of cisplatin-based regimens, new platinum-based regimens were tested in patients with ovarian germ cell tumors. Gershenson reported the efficacy of PVB in a small series of patients treated at UTMDACC (84). Among 15 patients, 7 received PVB in the adjuvant setting and 9 received the combination at the time of recurrence. Six of 7 patients treated with PVB upfront became long-term survivors. Among them, 3 women had optimally debulked stage III disease.

Subsequently, the PVB combination was evaluated prospectively in GOG protocol #45 (60). In this study, 47 of 89 patients with nondysgerminomatous ovarian tumors (53%) were disease-free with a median follow-up of 52 months. The latest treatment failure occurred at 28 months. Eight other patients had durable remissions with second-line therapy and a few other patients had nonprogressive or slowly progressive immature teratoma. Thus, the 4-year overall survival was approximately 70%. Of note, 29% of patients enrolled in this trial had received prior radiation or chemotherapy, which might

Table 25.3 Results of Second-Look Surgery in Patients Enrolled on GOG Protocols

Primary Surgery	Total Number	Positive Second-Look: Progression-Free/Total Number	Negative Second-Look: Progression-Free/Total Number
Completely resected tumor	45	7/7 ^a	37/38
Incompletely resected tumor	24	16/20 ^b	4/4
Teratoma present Teratoma absent	48	0/3 ^c	41/45

^a Five mature teratomas and 2 immature teratomas.

^b Sixteen mature teratomas and 4 immature teratomas.

Etoposide (VP-16)	100 mg/m ² days 1–5
Bleomycin	30 units IV weekly

^aThree to 4 courses given at 21-day intervals.

have affected negatively the overall outcome. As discussed previously, patients who were debulked to optimal disease fared better than those who were not. Histological type and marker elevation before treatment were not associated with adverse outcome. However, even among patients with nonmeasurable, and presumably small volume disease, and without prior treatment, 8 of 30 patients treated with PVB ultimately failed.

In testicular cancer, subsequent experience has documented that etoposide is at least equivalent to vinblastine and produces improved survival in patients with high tumor volume (82). Furthermore, the use of etoposide in place of vinblastine led to reduced neurologic toxicity, abdominal pain, and constipation. The latter 2 adverse effects are particularly important for patients with OGCTs, as many would have had recent abdominal surgery. These observations led to the evaluation of the combination of BEP (Table 25.4) in patients with ovarian germ cell tumors. In a series from UTMACC, long-term remissions were recorded in 25 of 26 patients treated with BEP (85). The only patient who succumbed to disease had been noncompliant with treatment, monitoring, and follow-up. In this series, 4 patients with measurable disease after surgery had complete remissions after BEP treatment. This led to a prospective GOG study evaluating BEP in patients with ovarian germ cell tumors (86). The regimen was highly effective, 91 of 93 enrolled patients being free of disease at follow-up. On the basis of these data, although BEP and VAC have not been prospectively compared, BEP emerged as the preferred regimen for patients with OGCTs. The inclusion of cisplatin in the treatment of ovarian tumors resulted indisputably in an improvement in survival and disease control, as shown by the results of GOG studies, as well as by other clinical series (87–89). These results of therapy are summarized in Table 25.5.

Differences in Outcome for Patients with Completely Resected Tumors Versus Advanced Stage Disease

It is clear that several prognostic factors impact the outcome of patients with OGCTs and that there are important differences

between testicular and ovarian germ cell neoplasms. Debulking surgery plays a central role in the management of ovarian tumors, but has a less important role in testicular cancer. In the hands of an experienced surgeon, the majority of women with ovarian tumors are debulked to minimal and often clinically undetectable disease before starting chemotherapy. Therefore, unlike patients with testicular cancer, most women who are candidates for chemotherapy have minimal or no residual disease. However, even in this circumstance, there seems to be little doubt that adjuvant therapy is appropriate in the majority of cases. The anticipated risk of relapse with surgery alone in patients with advanced disease is as high as 75% to 80%. Particularly, patients with embryonal carcinoma, endodermal sinus tumors, and mixed tumors containing these elements are considered to be at very high risk of recurrence without postoperative therapy. This risk can be minimized by the use of adjuvant chemotherapy. In GOG protocol #78, 50 of 51 patients with completely resected OGCTs remained free of disease when 3 cycles of BEP were given adjutantly. Other studies using cisplatin-based therapy have given similar results (Table 25.6). The recommended treatment for most patients (with the exception of patients with grade 1, stage IA immature teratoma, or stage IA dysgerminoma) is adjuvant chemotherapy with 3 courses of BEP. Virtually all patients with early stage or completely resected disease will survive after careful surgical staging and cisplatin-based adjuvant chemotherapy. More recently, clinical series and observations are beginning to suggest that surveillance with careful follow-up after surgery may be an acceptable alternative for carefully selected patients, as discussed below. Given the fact that surgery followed by chemotherapy is curative for most patients, this course of action should be taken only after very careful consideration. Further studies are needed in this area.

In contrast, most clinical series have shown worse clinical outcome for patients with metastatic disease or with incompletely resected tumors (see Table 25.7). Current clinical trials in testicular cancer separate patients with small tumor volume and a resultant excellent prognosis from those with bulky tumor or liver and brain involvement (90). Patients in the former group are usually complete responders to chemotherapy and long-term survivors, whereas only about 50% to 60% of the latter patients are cured. Hence, clinical trials for patients with good prognostic factors investigate shorter or less toxic chemotherapy aiming at minimizing toxicity (91), while preserving efficacy. In contrast, clinical trials for patients with high-risk disease have evaluated more intensive chemotherapy regimens with the goal of improving the likelihood of cure (92,93). For instance, high-dose chemotherapy (HDCT) with stem cell rescue was tested for patients with high-risk testicular cancer in a multi-institutional clinical protocol (ECOG protocol 3894).

Instituto Nazionale Tumori (13)	PVB	7/14 (50)
M.D. Anderson (19)	BEP	5/6 (83)

Note: BEP, bleomycin, etoposide, and cisplatin; GOG, Gynecologic Oncology Group; PVB, cisplatin, vinblastine, bleomycin.

Patients considered to have high risk for relapse were randomized to receive 4 cycles of BEP (control arm) versus 2 cycles of BEP followed by HDCT with autologous stem cell rescue in the form of 2 (tandem) courses using carboplatin, etoposide, and cyclophosphamide as a conditioning regimen (experimental arm). The 1-year durable complete response rate was 52% after BEP + HDCT and 48% after BEP alone ($p = 0.53$) (94). The results of the trial disproved the concept that more aggressive chemotherapy in the first-line setting improves outcome of high-risk testicular cancer patients when compared to standard dose BEP (95).

Dependable risk stratification, as the one used for testicular tumors, is not currently in use for OGCTs. The only clinical prognosticators for outcome of OGCTs remain stage at diagnosis and increase in tumor marker levels (96). Whether this reflects an inherent biologic difference between ovarian germ cell tumors and testis cancer or merely an underestimation of tumor volume because of intraperitoneal spread is not clear. In summary, with the exception of patients with grade 1, stage IA immature teratoma, or stage IA dysgerminoma, the available evidence supports that women with OGCT should receive 3 to 4 cycles of BEP chemotherapy after cytoreductive surgery. Therapy courses longer than 4 cycles are not supported, regardless of tumor volume.

Management of Residual or Recurrent Disease

The large majority of patients with OGCTs are cured with surgery and platinum-based chemotherapy. However, a small percentage of patients have persistent or progressive disease during treatment or recur after completion of treatment. Like in testicular cancer, these treatment failures are categorized as platinum-resistant (progression during or within 4 to 6 weeks of completing treatment) or platinum-sensitive (recurrence beyond 6 weeks from platinum-based therapy).

Most recurrences occur within 24 months from primary treatment. In a series from UTMDACC, 42 treatment failures were identified among 160 patients with ovarian germ cell tumors treated between 1970 and 1990 (97). Treatment failure in these patients was attributed to inadequate surgery in 14 patients, inadequate radiation in 5 patients, inadequate chemotherapy in 16 patients (underdosing and noncompliance), treatment-related toxicity in 1 patient, and unidentifiable causes in 6 patients. A significant number of patients included in this series had received VAC-based chemotherapy, which accounted for the higher than expected rate of recurrence.

Given the high curability rate of OGCTs with primary treatment, the management of recurrent disease represents a complex and often difficult issue, and preferably should be performed in a specialized center. Data to guide the management of patients with recurrent OGCTs are scant and largely extrapolated from the clinical experience with testicular cancer. The single most important prognostic factor in patients with testicular cancer is whether or not they are refractory to cisplatin. The likelihood of cure with high-dose salvage therapy in patients who relapse from a complete remission after initial therapy is as high as 60% or more. On the other hand, in patients who are truly cisplatin-refractory, the likelihood of long-term survival and cure is significantly less. However, up to 30% to 40% of these patients can become long-term survivors. Approximately 30% of patients with recurrent platinum-sensitive testicular cancer can be salvaged with second-line chemotherapy (VeIP: vinblastine, ifosfamide, platinum) (92). However, there is now strong evidence that high-dose therapy with carboplatin, etoposide with or without cyclophosphamide or ifosfamide, and stem cell rescue is superior to standard dose salvage therapy for these patients (98,99). Generally, in patients who are not cisplatin-refractory

one course of standard dose therapy, usually cisplatin, vinblastine, and ifosfamide, is given. If an initial response is seen, then 2 subsequent courses of high-dose chemotherapy (carboplatin and etoposide) with stem cell rescue are given (100). A recent report from Indiana University describes this approach among 184 patients with recurrent testicular cancer. At a median follow-up of 48 months, 116 patients were in complete remission. Remarkably, of the subgroup of 40 patients who were platinum refractory, 18 are disease-free after high-dose chemotherapy (101). While this approach has not been prospectively tested in women with recurrent platinum-sensitive OGCTs, because of the small numbers of patients, the concepts are very similar and support the use of high-dose therapy in this setting. Referral to a specialized center for management of recurrent disease is desirable.

Active agents in the setting of recurrence after high-dose chemotherapy include ifosfamide, taxanes, gemcitabine, and oxaliplatin (102–105). In a phase II trial from Indiana University, the combination of gemcitabine and paclitaxel induced objective responses in 10 of 31 patients who had recurred after high-dose chemotherapy. Of those, 5 patients were free of disease 2 years after treatment (105). The combination of gemcitabine and oxaliplatin (GemOx) induced a 46% response rate in a group of 31 patients with recurrent germ cell tumors. Over 60% of these patients were platinum-resistant or refractory (106). Referral for treatment with investigational agents for recurrent, refractory OGCTs is appropriate.

Immediate Toxicity of Chemotherapy

Acute adverse effects of chemotherapy can be substantial and these patients should be treated by physicians experienced in their management. About 25% of patients develop febrile neutropenic episodes during chemotherapy and require hospitalization and broad-spectrum antibiotics (107). Cisplatin can be associated with nephrotoxicity. This can be avoided by ensuring adequate hydration during and immediately after chemotherapy and by avoidance of aminoglycoside antibiotics. Bleomycin can cause pulmonary fibrosis (107). Pulmonary function testing is frequently used to follow these patients. However, the value of carbon monoxide diffusion capacity to predict early lung disease has been challenged (108). The most effective method for monitoring patients with germ cell tumors is careful physical examination of the chest. Findings of early bleomycin lung disease are a lag or diminished expansion of one hemithorax or fine basilar rales that do not clear with cough. These findings can be very subtle but if present immediate discontinuation of bleomycin should be mandated. It is important to note that randomized trials in good prognosis testicular cancer have suggested that bleomycin is an important component of the treatment regimen, particularly if only 3 courses of therapy are given (109,110). Other randomized trials have shown that carboplatin is inferior to cisplatin and cannot be substituted for cisplatin without worsening therapeutic outcome (111,112).

Patients with advanced OGCTs should receive 3 to 4 courses of treatment given in full dose and on schedule. There is presumptive evidence in testicular cancer that the timeliness of chemotherapy may be associated with outcome. Thus, treatment is given regardless of hematological parameters on the scheduled day of treatment. The impact of the hematopoietic growth factors (G-CSF, GM-CSF) on the management of the myelosuppressive complications of this chemotherapy has not been precisely defined. As most patients will not develop neutropenic fever or infection, hematopoietic growth factors are not routinely necessary (113). It is reasonable to use hematopoietic growth factors to avoid dose reductions for patients with previous episodes of neutropenic fever or in unusually ill patients who are at a higher risk of myelosuppressive complications, or those who received

Table 25.7 A Typical Antiemetic Regimen

Granisetron 1 mg IV 30 min prior to cisplatin daily for 5 days

or

plus

Dexamethasone 20 mg IV 30 min prior to cisplatin on days 1 and 2

plus

Aprepitant 125 mg PO on day 1 and 80 mg PO on days 2 and 3, prior to cisplatin infusion

prior radiotherapy. Modern antiemetic therapy, an example of which is shown in Table 25.7, has greatly lessened chemotherapy-induced emesis. By following these guidelines and providing supportive care as indicated, virtually all patients can be treated on schedule, in full or nearly full dose. Chemotherapy-related mortality should be less than 1%. Indeed in GOG protocol #78, there were no toxic deaths among 93 patients treated. Late effects of chemotherapy are discussed below.

Immature Teratoma

The situation of patients with immature teratoma (IT) is more complex. Immature teratomas are categorized as grade 1, 2, or 3 depending on the amount of immature neuroepithelium in the tumor, based on Thurlbeck and Scully's system, which was modified by Norris (2). Our current appreciation of recurrence risk in these patients is based on an early study by Norris (3). This report demonstrated that prognosis of patients with IT directly relates to tumor grade. Specifically, only 1 of 14 patients with grade 1 IT recurred, while 13 of 26 patients with grade 2 and 3 tumors recurred. This study set the current standard of care for women with stage I teratoma, which is surveillance for grade 1 immature teratoma and adjuvant chemotherapy with 3 courses of BEP for patients with grade 2 and 3 tumors (4). However, a significant limitation of the Norris report is the probable underestimation of tumor stage. Hence, in the modern era of complete surgical staging of ovarian neoplasms, it might be appropriate to reconsider the role of routine adjuvant therapy in these patients. Obviously, such an approach must be done with great caution, as surgery followed by adjuvant therapy cures virtually all patients with localized high-grade teratoma. However, it is possible that the risk of relapse is sufficiently low in a defined population of well-staged patients, to warrant clinical observation. This could be accomplished with careful follow-up, such that relapsing patients would be diagnosed with small volume tumor and cured with subsequent salvage chemotherapy. While some issues are different in testicular cancer, a deferral of chemotherapy has been shown to be an appropriate therapeutic alternative for resected stage II tumors and clinical stage I disease. Surveillance for stage I ovarian IT is supported by experience from several groups.

First, an Intergroup study of the Pediatric Oncology Group and the Children's Cancer Group reported that surveillance after complete surgical resection in 41 girls with ovarian immature teratoma was sufficient (114,115). Only one recurrence (which was salvaged with BEP) was noted during 24 months of follow-up. Of note is that in this series, 13 patients had grade 2 and 3 IT, and 10 patients had mixed tumors containing IT plus yolk sac tumor (5).

Second, investigators at Mount Vernon and Charing Cross Hospitals in England have observed 15 patients with stage IA tumors after initial surgical treatment (116). Of these, 9 patients had grade 2 or 3 immature teratoma and 6 had elements of endodermal sinus tumor. There were 3 recurrences in this series, 1 of 9 in the pure immature teratoma group and 2 of 6 in the mixed histology group. Two of these patients were salvaged with chemotherapy and one patient died of pulmonary embolus. Of note is that the patient who died became pregnant 4 months after diagnosis and could not be followed adequately due to her pregnancy.

Third, investigators at the University of Milan reported the clinical outcome in a group of 32 patients with pure ovarian IT followed prospectively (117). In this group, 9 patients had grade 2 and 3 stage IA immature teratomas and were treated with surgery and intensive surveillance. Only 2 recurrences were noted in this group. They consisted of 1 case of mature teratoma and 1 case of gliosis. The mature teratoma was resected and the patient with gliosis was followed without treatment. Both patients are alive and well, and never received chemotherapy. Furthermore, among 4 patients with stage IC tumors treated with surgical resection and surveillance, there was one case of gliosis and one recurrence with mature tissue, which was resected (no chemotherapy). All patients are currently free of disease.

When considering these issues, it is important to not overstate the toxicities of adjuvant therapy. In earlier times, chemotherapy-induced emesis was a very significant problem. However, with modern antiemetics such as the 5HT₃ antagonists, emesis is greatly reduced and, while unpleasant, rarely is a major complication of chemotherapy. Acute treatment-related mortality, particularly from bleomycin-related lung disease, is also rare. Nonetheless, chemotherapy is certainly unpleasant, produces universal alopecia, occasionally severe emesis, and has a remote risk of serious acute toxicity and drug-induced mortality. Considering this information, it may be appropriate to consider surveillance with careful follow-up in well-staged adult patients with ovarian stage IA immature teratoma. While this concept is supported by evidence derived from the pediatric literature and 2 small clinical series as discussed, this hypothesis has not been tested prospectively and should be approached with caution.

DYSGERMINOMA

Dysgerminoma is the female equivalent of seminoma. This disease differs from its nondysgerminomatous counterparts in several respects. First, it is more likely to be localized to the ovary at the time of diagnosis (stage I). Bilateral involvement is more common, as is its spread to retroperitoneal lymph nodes. While less relevant now than before the era of modern chemotherapy, dysgerminoma is very sensitive to radiation (40,50,118).

Observation for Stage I Tumors

As many as 75% to 80% of dysgerminoma patients used to be considered stage I at diagnosis (49,119). However, with more precise surgical staging, as done currently, the true figure is probably somewhat less. Traditionally, most of these women received postoperative radiotherapy. Given the fact that pelvic radiotherapy is associated with high incidence of gonadal dysfunction and sterility, an alternative option for low-risk patients who desire to maintain fertility is postsurgical clinical surveillance (120). In a previous era, clinical observation was deemed appropriate for women with tumors less than 10 cm and without contralateral ovarian involvement; while adjuvant radiotherapy was

recommended for larger tumors (121). The size-based distinction was subsequently called into question (119,122). In a series reported by LaPolla et al., 7 of 9 patients with stage IA dysgerminoma followed without postoperative radiotherapy remained disease-free (119). All but 1 had tumors greater than 10 cm. In another report, among 14 patients with stage IA dysgerminoma treated with surveillance, 5 recurred. Of those, 4 patients were salvaged with radiation and 1 was salvaged with radiation followed by chemotherapy. All stage IA patients are alive, free of disease (118). Similarly, Gordon reported that the 5-year survival among 72 patients with stage IA pure dysgerminoma treated conservatively was 95% (40). The recurrence rate in this case series was 17%, with 4 deaths attributable to disease. However, in this series salvage chemotherapy was offered to only 1 patient, which may explain the unfavorable outcomes. A report from Mount Vernon and Charing Cross Hospitals quoted 2 relapses among 9 patients with stage IA dysgerminoma treated with observation. Both were cured with salvage chemotherapy (123). A summary of reports using observation after surgery in stage I dysgerminoma is presented in Table 25.8.

Currently, patients with stage IA dysgerminoma can be observed after unilateral salpingo-oophorectomy, regardless of the size of the primary tumor, if preservation of fertility is an issue. Careful follow-up is required, because as many as 15% to 25% of patients will experience a recurrence. However, because of the tumor's chemosensitivity, virtually all patients can be salvaged successfully at the time of recurrence, if adequate follow-up and early detection have been accomplished.

Radiation Therapy

In the past, many stage I patients and all patients with higher stage tumors received radiotherapy. DePalo and associates recommended radiation therapy for all stage I–III patients (49). Radiation therapy was delivered to the ipsilateral hemipelvis (with shielding of the contralateral ovary and the head of the femur) and to the paraaortic nodes. A single field with the upper limit at T10–T11 and the lower limit at L4–L5 level was used. For stage III retroperitoneal disease, curative radiation therapy was set up in the same fashion as for stage I, with the addition of a prophylactic field including the mediastinum and supraclavicular nodes. In the presence of peritoneal involvement, the whole abdomen and pelvis, mediastinum and supraclavicular

Table 25.8 Results of Clinical Surveillance after Surgery in Patients with Stage IA Dysgerminoma

Institution	Period	Progression-Free/Total Number (%)	Overall Survival/Total Number (%)

Abbreviation: AFIP, Armed Forces Institute of Pathology.

nodes were irradiated. Typically, 30 Gy (7.5 to 9 Gy/week) were given as prophylactic irradiation. For curative irradiation, 35 to 40 Gy total dose was given and a boost (10 Gy) was delivered to involved nodes. When irradiating above the diaphragm, DePalo gave 30 additional Gy 3 to 6 weeks after completion of irradiation below the diaphragm. When irradiating the entire abdominal cavity, the fields were similar to those used for epithelial tumors. They gave a total dose of 25 Gy (6 to 7.5 Gy/week). The kidneys were shielded. Similar techniques were reported by Lawson and Adler (124) and others (121,125,126).

Currently, most investigators consider this form of treatment obsolete because of the small number of patients who would derive a potential benefit and because of the subsequent reduced tolerance for chemotherapy in this population. Furthermore, considering the recent developments in the field of chemotherapy, it is accepted that primary chemotherapy is equally or more effective than irradiation of extensive normal tissue volumes, and is substantially less likely to compromise salvage therapy when patients relapse after primary therapy. Given that most patients will be cured of their ovarian tumors, and that most patients are young at the time of diagnosis, some consideration should also be given to the delayed carcinogenic effects of intermediate dose radiation. Although this issue has not been specifically addressed in women with OGCTs, it is logical to extrapolate from the experience of younger women who are frequently successfully treated with radiation for cancer of the uterine cervix, and in whom the risk of second malignancies (both within and remote from the primary radiation fields) is increased 2 or 3 decades following successful initial treatment (127).

Results of radiation therapy are reasonably good. DePalo et al. reported that all 13 stage I patients (12 stage IA and 1 with stage IB) treated with radiotherapy were alive and free of disease with a median follow-up of 77 months (49). The 5-year relapse-free survival for 12 stage III patients was 61.4% and the overall survival was 89.5%. Median follow-up was 67 months. Only 1 death was reported in this group. Earlier, DePalo et al. reported 100% overall 5-year survival and 90% recurrence-free 5-year survival in 31 stage IA, IB, and IC patients (49). At 4 years, the overall survival was 80% and the recurrence-free survival was 57% in stage III patients. Lawson and Adler reported that 10 of 14 stage I–III patients were alive with a median follow-up of 54 months (124). In this small series there was no correlation between survival and the stage of disease or the size of the primary tumor. Others reported similar results, with overall progression-free rates varying between 70% to 90% (see Table 25.9) (50,51). However, despite the remarkable radiosensitivity of dysgerminoma, radiotherapy is rarely performed nowadays, since chemotherapy is equally or more effective, less toxic, and less likely to compromise gonadal function.

Chemotherapy

There is an increasing amount of information available about chemotherapy for patients with advanced ovarian dysgerminoma. Dysgerminoma is very responsive to cisplatin-based chemotherapy, even more so than tumors other than dysgerminoma (85,128). Since 1984, patients with advanced dysgerminoma were eligible for GOG protocols. Patients enrolled on these studies received 3 to 4 courses of PVB or BEP. In a combined analysis, 20 patients were evaluated (129). All had stage III or IV disease and most of them had suboptimal (greater than 2 cm) residual tumor. Overall, with a median follow-up of 26 months, 19 of the 20 women were disease-free. Among 11 patients with clinically measurable tumor, 10 had complete responses to chemotherapy. Fourteen patients who underwent second-look laparotomy had completely negative results. Thus, it appears that

nearly all patients with advanced dysgerminoma treated with chemotherapy will be durable complete responders.

Considering that patients with stage III dysgerminoma would require extensive radiation and still carry a risk of failure and that such patients probably fare worse with subsequent chemotherapy, it is clear that these patients should be treated primarily with chemotherapy. For most, the preferred adjuvant therapy is BEP. This regimen almost invariably prevents recurrence in nondysgerminomatous tumors and certainly will do so in dysgerminoma. Most patients treated with BEP will retain fertility. An alternative regimen tested by the GOG consists of a 3-day regimen with carboplatin and etoposide. On this protocol, all 39 patients with pure dysgerminoma remained free of disease at a median follow-up of 7.8 years (130). Although highly active, this regimen is not recommended for routine use due to significantly less experience accumulated with its use and the concern that this regimen is not as effective in tumors containing nondysgerminomatous elements.

The implications of elevated hCG or AFP levels in patients with dysgerminoma should be emphasized. These tumor markers are usually increased in patients with nondysgerminomatous tumors. Therefore, AFP elevation denotes the presence of elements other than dysgerminoma and treatment should be tailored accordingly. An elevated hCG level can be occasionally seen in pure dysgerminoma. This finding should not alter therapy, but it should prompt reexamination of the tumor specimen to determine whether syncytiotrophoblastic cells are present or if the tumor contains nondysgerminomatous elements.

In summary, the majority of dysgerminoma patients have stage I disease at diagnosis. These patients can be treated with unilateral salpingo-oophorectomy and if fertility is an issue, they can be observed carefully with regular pelvic examinations, abdominal computerized tomography, and tumor markers including LDH. Fifteen percent to 25% of patients observed will experience recurrence and will require chemotherapy. In patients with more advanced disease, the risk of recurrence is significant enough to warrant adjuvant treatment. Alternatives

are chemotherapy or radiation. For the majority of patients, chemotherapy is the clear choice because of ease of administration, predictable and minimal toxicity, and fertility-sparing properties. Chemotherapy is also recommended for patients with metastatic or incompletely resected tumor and for patients who recur after previous radiotherapy. Radiation might be considered as initial treatment in unusual circumstances, such as older patients or in those with serious concomitant illness that would preclude the use of systemic chemotherapy.

LATE EFFECTS OF TREATMENT

As the prognosis of patients with OGCTs has dramatically improved with the evolution of modern combination chemotherapy, attention is focused on late effects of therapy. There is a considerable body of literature on the late effects of treatment in testicular cancer patients, yet the information available for women with OGCTs remains scant. However, many analogies can be drawn.

Sequelae of Surgery

Young patients with OGCTs undergo at least one, if not multiple, surgical procedures. Although there is no available information on the long-term effects of surgery on these patients, future infertility related to pelvic surgery with subsequent peritoneal and tubal adhesions is well described. Therefore, meticulous surgical technique and avoidance of unnecessary operative maneuvers (e.g., biopsy of a normal contralateral ovary) are required for preventing future complications (55,131,132). Another cause of infertility in this population is unnecessary bilateral salpingo-oophorectomy and hysterectomy. The M.D. Anderson series included several patients who underwent surgical sterilization without a good indication before referral to their center. It is expected that this phenomenon will become less frequent, as information concerning the outcome of treated patients with OGCTs is more widely disseminated. In a series from Milan, among 55 patients treated with fertility-sparing surgery, without further chemotherapy, 12 out of 12 patients who attempted conception became pregnant and 12 normal deliveries were recorded (133). Two additional pregnancies occurred in this group and resulted in termination, one of which was due to in-uterus detection of fetal malformation. Recently, Gershenson reported the findings of GOG protocol 9901 (134). Among 132 survivors of ovarian germ cell tumors, treated with surgery and platinum-based chemotherapy, 71 patients had fertility-sparing procedures. Of those fertile survivors, 62 (87.3%) maintained menstrual periods and 24 survivors reported 37 successful pregnancies. Although the survivors reported increased incidence of gynecological problems and diminished sexual pleasure, they also tended to have stronger, more positive relationships with their significant others (134).

As with any group of patients with a history of pelvic surgery, patients with OGCTs may develop functional cysts in the residual ovary. Muram et al. reported his experience with 27 patients with ovarian germ cell tumors who underwent unilateral salpingo-oophorectomy and were followed for 12 to 215 months after completion of therapy (135). Of the 18 patients who maintained ovarian function, 13 (72%) developed functional cysts during follow-up. A trial of oral contraceptives and serial ovarian surveillance with sonography is helpful in distinguishing functional cysts from tumor recurrence.

Sequelae of Radiation Therapy

There is limited information about the late effects of radiotherapy in dysgerminoma patients. In a review of the late effects of

radiotherapy in patients receiving abdominal therapy for ovarian dysgerminoma at UTMDACC, there was a small increase in reported dyspareunia and the number of bowel movements (120). Somewhat surprisingly, at a median follow-up of 12 years, none of the 43 patients treated with radiotherapy developed small bowel obstruction. No other significant intestinal or bladder problems were recorded. As expected none of the patients treated with radiation conceived. Although the late effects of radiotherapy in this population seem to be few with the notable exception of gonadal failure (136), these observations may soon be of only historical interest. As discussed earlier, there has been a strong trend away from radiotherapy and toward chemotherapy as the preferred postoperative therapy of dysgerminoma patients. Concern over preservation of gonadal function has been the driving force behind this transition (48,137).

Sequelae of Chemotherapy

The evolutionary development and refinement of combination chemotherapy have resulted in the cure of a high percentage of patients with chemosensitive tumors, such as lymphomas, testicular cancer, gestational trophoblastic disease, and malignant ovarian germ cell tumors. Within the last few years, several reports have described the long-term effects of chemotherapy in cancer survivors. As expected, most reports refer to the more common lymphomas and testicular cancers.

A recently recognized effect of chemotherapy used for the treatment of germ cell tumors is the risk of secondary malignancies. The epipodophyllotoxins teniposide and etoposide are associated with the development of acute myelogenous leukemia (AML) with certain morphologic and cytogenetic features (138–142). This treatment complication appears to be dose- (138,139) and schedule-dependent (141). Of 348 male germ cell tumor patients receiving 3 to 4 courses of BEP as first-line therapy at Indiana University, 2 developed etoposide-related leukemia. None of the 67 patients who received only 3 courses developed AML (138). Similarly, in the study reported by Pedersen-Bjergaard et al., 5 out of 212 patients developed acute leukemia or myelodysplastic syndrome after etoposide therapy (139). However, all patients who developed AML received more than 2000 mg/m² of etoposide. None of the 130 patients who received less than this dose developed AML. Morphologically, these leukemias are monocytic or myelo-monocytic (M4 or M5). Characteristic chromosomal translocations (mostly involving the 11q23 region) are frequently, but not always, present. Leukemia after etoposide treatment occurs within 2 to 3 years compared to alkylating agent-induced AML, which has a longer latency period. Late occurrence of chronic myelogenous leukemia after treatment of testicular cancer was reported (143). In the GOG protocol testing the efficacy of BEP in women with ovarian germ cell tumors, 1 case of AML was recorded among 91 patients treated (86). An additional case of lymphoma was diagnosed during follow-up in this series, yet a correlation between chemotherapy and lymphoproliferative disorders has not been reported to date. Taking these issues into account, most clinicians consider BEP as the chemotherapy regimen of choice. The incidence of second neoplasms is quite low, particularly in patients receiving low cumulative etoposide doses. The continued use of etoposide over vinblastine is based on its superior efficacy demonstrated in testis cancer (82). Furthermore, vinblastine-induced abdominal pain and ileus are troublesome for some patients, particularly for those who underwent abdominal surgery, such as women with ovarian germ cell tumors. The risk/benefit ratio continues to favor etoposide over vinblastine.

There also continues to be considerable focus on the long-term effects of chemotherapy on gonadal function. Studies of patients with a variety of cancers suggest that, although ovarian

dysfunction or failure is a risk of chemotherapy, the majority of survivors can anticipate normal menstrual and reproductive function (144–146). Factors such as old age at initiation of therapy, greater cumulative drug dose (147), and longer duration of therapy (146) have an adverse effect on future gonadal function. Successful pregnancies after treatment with combination chemotherapy have been well documented in other types of malignancies, including Hodgkin's disease, nonHodgkin's lymphomas, and leukemia. There are similar reports in patients with malignant OGCTs (133,148–151).

In a review of the UTMDACC series (148), 27 (68%) of 40 patients who had retained a normal contralateral ovary and uterus maintained regular menses consistently after completion of chemotherapy and 33 (83%) were having regular menses at the time of follow-up. Of 16 patients who had attempted to become pregnant, 12 were successful. One patient underwent an elective first-trimester abortion and the other 11 patients bore 22 healthy infants over time, none of which had a major birth defect. In a series from Milan, among 169 patients with ovarian germ cell tumors, 138 underwent fertility-sparing surgery, and of these, 81 underwent adjuvant chemotherapy (133). After treatment, all but one woman recovered menstrual function and 55 conceptions were recorded. Forty normal full-term babies were delivered. There were 4 babies with congenital malformations, 1 in a patient who did not receive chemotherapy and 3 in women who had received chemotherapy (the difference was not statistically significant).

The GOG recently completed an analysis evaluating the quality of life and psychosocial characteristics of survivors of ovarian germ cell tumors compared to matched controls. In this analysis, the survivors appeared to be well adjusted, were able to develop strong relationships, and were free of significant depression (152). The impact on fertility was modest or none in patients undergoing fertility-sparing surgeries (134). OGCT survivors appeared to be free of any major physical illnesses at a median follow-up of 10 years, as compared to matched controls. The only differences were higher rates of reported hypertension (17% vs. 8%, $p = 0.02$), hypercholesterolemia (9.8% vs. 4.4%, $p = 0.09$), and hearing loss (5.3% vs. 1.5%, $p = 0.09$) compared with controls (153). Among chronic functional problems, numbness, tinnitus, nausea elicited by reminders of chemotherapy (vs. general nausea triggers for controls), and Raynaud's symptoms were reported more frequently by survivors. Interestingly, late effects of treatment are more pronounced among children receiving treatment for germ cell tumors (154). Specifically, neurotoxicity, growth abnormalities, pulmonary toxicity, and gastrointestinal toxicity have been reported in a higher proportion than in adult patients. Despite persistence of a few sequelae of treatment, in general, OGCT survivors enjoy a healthy life comparable to that of controls, justifying administration of curative treatment in full and timely dosing.

SUMMARY

Virtually all patients with early-stage, completely resected OGCTs survive after careful surgical staging and 3 courses of adjuvant BEP. Furthermore, up to 80% of patients with incompletely resected or advanced tumors are expected to be long-term survivors. Acute toxicity of treatment is relatively modest. An important, but fortunately unusual late complication of treatment is etoposide-induced leukemia. However, patients receiving the usually administered cumulative dose of etoposide are at low risk for developing AML. Otherwise, late consequences of chemotherapy are limited. Efforts should concentrate on fertility preservation for patients who desire subsequent pregnancies.

The majority of dysgerminoma patients have stage I disease at diagnosis. These patients usually can be treated with unilateral salpingo-oophorectomy and careful postoperative observation without adjuvant treatment. Chemotherapy is offered at the time of recurrence. In patients with more advanced but resected disease, the risk of recurrence is significant enough to warrant up-front adjuvant treatment, which for most patients is chemotherapy because of its near universal effectiveness and limited impact on fertility. In patients with incompletely resected tumor or for patients who recur after previous radiation, chemotherapy similar to that given for tumors other than dysgerminoma is appropriate.

Surgery continues to have a pivotal role in the management of all patients with OGCTs. Initial careful surgical staging is important for selection of appropriate subsequent therapy. Second-look laparotomy is not necessary in patients who have

no residual tumor after their initial surgical procedure and who receive adjuvant chemotherapy. This procedure also does not seem warranted in patients with advanced tumors without elements of teratoma. The judicious use of surgery followed by chemotherapy will cure the majority of patients with ovarian germ cell tumors at the expense of minimal and predictable immediate and late toxicities. In most circumstances fertility can be preserved.

ACKNOWLEDGMENT

This chapter is dedicated to Stephen D. Williams, MD (1947–2009), founding director of the Indiana University Simon Cancer Center, outstanding oncologist, mentor, and friend.

Ovarian Sex Cord–Stromal Tumors

DAVID M. GERSHENSON ■ SEAN C. DOWDY ■
ROBERT H. YOUNG

The intraovarian matrix that supports the germ cells and is covered by the surface epithelium consists of cells originating from the sex cords and mesenchyme of the embryonic gonad. Granulosa cells and Sertoli cells, generally considered to be homologous, are derived from the sex cord cells, whereas the pluripotential mesenchymal cells are the precursors of the theca cells, Leydig cells, and fibroblasts. Neoplastic transformation of these cellular constituents, either singly or in various combinations collectively, results in neoplasms that are termed sex cord-stromal tumors (SCSTs). The classification of the SCSTs provides the template from which this chapter endeavors to stratify and define these tumor entities according to their morphologic characteristics (Table 26.1).

The SCSTs are estimated to account for approximately 7% of all malignant ovarian neoplasms (1). Although SCSTs account for a decreasing proportion of all ovarian malignancies with advancing age, the annual age-related incidence continues to increase through the seventh decade of life (2). Overall, the majority of these tumors are benign or of low malignant potential and are associated with a favorable long-term prognosis. In addition, a significant proportion of SCSTs are diagnosed in patients younger than age 40 years and have the potential to produce a variety of steroid hormones. Hence, adequate knowledge of the natural history of each of these tumors is imperative to diagnose and individualize appropriately definitive surgical and adjuvant therapy.

SCSTs account for nearly 90% of all functioning ovarian neoplasms (3). With the exception of fibromas, the clinical presentation of patients with SCSTs is frequently governed by the clinical manifestations resulting from the endocrinologic abnormalities. Excessive estrogen production, whether from increased tumor synthesis or peripheral conversion of androgens, influences end-organ responses, which are usually age-dependent and can range from isosexual precocious puberty to menometrorrhagia to postmenopausal bleeding. In addition, the associated risks for endometrial cancer and possibly breast cancer must be recognized (4–6). Conversely, the rapid onset of signs ranging from early defeminization to frank virilization heralds a hyperandrogenic state. Elevated circulating levels of testosterone and/or androstenedione provide strong evidence for the presence of an SCST. Although granulosa cell, theca cell, and Sertoli cell tumors are generally considered to be estrogenic, and Sertoli-Leydig cell and steroid cell tumors are predominantly androgenic, the functional endocrinologic capacities of these tumors are impossible to predict based on their morphologic features. It should also be noted that miscellaneous ovarian tumors, both primary and metastatic, that are not in the SCST family may be androgenic or estrogenic if their stroma is stimulated to undergo luteinization.

GRANULOSA CELL TUMORS

Although granulosa cell tumors (GCTs) of the ovary were initially described by Rokitansky in 1859 (7), the etiopathogenesis of these neoplasms remains ill defined. At least in part, this is a reflection of the low incidence of GCTs, and hence the limited number of cases managed at any single institution. Although molecular aberrations crucial to the pathogenesis of GCTs have been elucidated recently, to our knowledge there are no recognized risk factors for their development (4,8). Reproductive factors, including the use of fertility-promoting agents and oral contraceptives, do not correlate consistently with the development of disease. Unkila-Kallio et al. (9) studied a possible link between fertility-promoting agents and GCTs using the nationwide Finnish Cancer Registry. They analyzed the occurrence of GCTs in Finland during the time period 1965 to 1994 against sales statistics for ovulation inducers. The incidence of GCTs declined by nearly 40% from 1965–1969 to 1985–1994 despite a 13-fold increase in the use of clomiphene citrate and a 200-fold increase in human menopausal gonadotropin use; oral contraceptive use increased fivefold. No hereditary predisposition for any of the SCSTs has been identified (10). Of note, a recent case report described the occurrence of adult GCTs in 2 first-degree relatives (11).

GCTs comprise 5% of all ovarian malignancies, but account for approximately 70% of malignant SCSTs (4–6, 12–19). The annual incidence of GCTs in the United States and other developed countries varies from 0.4 to 1.7 cases per 100,000 women (5,6,8,18,20,21). Quirk and Natarajan reported histology-specific age-adjusted ovarian cancer incidence rates that were standardized to the recently adopted year 2000 U.S. standard population (22). They utilized data gathered from the Surveillance, Epidemiology, and End Results (SEER) Program for the years 1992–1999. Out of a total of 23,484 microscopically confirmed cases of primary ovarian cancer, 293 (1.2%) were of sex cord–stromal origin. Although GCTs have been diagnosed from infancy through the tenth decade of life, the peak incidence for these tumors occurs during the perimenopausal decade. The average age at the time of diagnosis in over 750 cases was 52 years (4–6,13,15–18). Considering that GCTs occurring after the third decade of life appear to be histologically distinct in most instances from those occurring in children and younger adults, the clinical and pathologic characteristics for the juvenile and adult GCTs will be addressed separately.

Table 26.1 **Classification of Sex Cord–Stromal Tumors**

Granulosa-Stromal Cell Tumors
Granulosa cell tumor
Adult type
Juvenile type
Tumors in the thecoma-fibroma group
Thecoma
Fibroma-fibrosarcoma
Sclerosing stromal tumor
Sertoli-Stromal Cell Tumors
Sertoli cell tumor
Leydig cell tumor
Sertoli–Leydig cell tumor
Well differentiated
Of intermediate differentiation
Poorly differentiated
With heterologous elements
Retiform
Mixed
Sex Cord Tumor with Annular Tubules
Unclassified
Gynandroblastoma
Steroid cell tumors
Stromal luteoma
Leydig cell tumor
Hilus cell tumor
Leydig cell tumor, nonhilus type
Steroid cell tumor not otherwise specified

Granulosa Cell Tumors: Adult Type

Adult-type granulosa cell tumors (AGCTs), as histologically described below, account for 95% of all GCTs. The majority of patients will present with one or a combination of the following clinical symptoms: abnormal vaginal bleeding, abdominal distention, and abdominal pain (5,6,15–18,23). The latter symptoms are most frequently attributable to the gross size of the tumor at the time of diagnosis, with the majority exceeding 10 cm in diameter and many exceeding 15 cm (5,16,18). In one series, 12% had ascites at diagnosis (23). In many series, menometrorrhagia, oligomenorrhea, or amenorrhea in premenopausal women or bleeding in postmenopausal women is the most common reason for seeking medical assistance. These and other clinical manifestations such as breast tenderness, uterine myohypertrophy, and endometrial hyperplasia are consistent with the presence of an estrogen-secreting tumor.

The endocrine function of AGCTs, specifically the production of estrogens, has been repeatedly demonstrated by assessment of the end organ, the endometrium, and measurements of peripheral levels of estrogen before and after surgery. In a detailed retrospective analysis of endometrial specimens from patients (n = 69) with GCTs, Gusberg and Kardon (24) observed histologic features consistent with unopposed estrogen, including atypical adenomatous hyperplasia in 42% of the evaluated cohort, adenocarcinoma *in situ* (4) in 5%, and invasive adenocarcinoma in

22%. Similarly, Evans et al. (4) noted endometrial hyperplasia in 55% and adenocarcinoma in 13% of their GCT study population. Other investigators have corroborated the high prevalence of glandular hyperplasia and have reported adenocarcinoma frequencies ranging from 3% to 27% (5,6,13,15–18,25,26). Selective ovarian venous catheterizations during surgery have documented hormonal production, including the secretion of large quantities of estrogen from the ovary harboring the GCT. The return of serum estrogen to physiologic levels after definitive treatment has been witnessed repeatedly. Occasionally, patients with GCTs present with endometrial changes (decidual reaction of the stroma or secretory characteristics of the glands) consistent with tumor production of progesterone (27). Rarely, virilizing changes such as oligomenorrhea, hirsutism, and other masculinizing signs may accompany GCTs (28–30).

Pathology

AGCTs have an average diameter of approximately 12 cm, but a subset, 10%–15% of the cases, are small and not appreciated on pelvic examination (31). Most characteristically, they are predominantly cystic, with numerous locules filled with fluid or clotted blood and separated by solid tissue (Fig. 26.1), or they are solid, with large areas of hemorrhage. The solid tissue may be gray-white or yellow and soft or firm. A rare tumor is cystic, usually thin walled, but occasionally thick walled, and multilocular or unilocular (29).

Microscopic examination reveals an almost exclusive population of granulosa cells or, more often, an additional component of theca cells, fibroblasts, or both. The granulosa cells grow in a wide variety of patterns. The better-differentiated tumors usually have microfollicular, macrofollicular, insular, or trabecular patterns. The microfollicular pattern is characterized by numerous small cavities (Call-Exner bodies) (Fig. 26.2) that may contain eosinophilic fluid, one or a few degenerating nuclei, hyalinized basement-membrane material, or, rarely, basophilic fluid. The microfollicles are typically separated by well-differentiated granulosa cells that contain scanty cytoplasm and pale, angular or oval, often grooved nuclei arranged haphazardly in relation to one another and to the follicles. The uncommon macrofollicular pattern is characterized by cysts lined by well-differentiated granulosa cells beneath which theca cells are present. The

FIGURE 26.1. Granulosa cell tumor: The sectioned surface is composed predominantly of multiple cysts filled with blood.

FIGURE 26.2. Granulosa cell tumor; adult type, microfollicular pattern. Several nests of granulosa cells with small oval and angular nuclei enclose multiple Call-Exner bodies.

trabecular and insular forms of GCTs are characterized by bands and islands of granulosa cells separated by fibromatous or thecomatous stroma. The less well-differentiated forms of the adult granulosa cell tumor typically have a water silk (moiré silk), gyriform, or diffuse (sarcomatoid) pattern alone or in combination. The first 2 patterns are manifested by parallel undulating or zigzag rows of granulosa cells, generally in single file, whereas the diffuse form is characterized by a monotonous, patternless cellular growth. In some adult granulosa cell tumors, the neoplastic cells have moderate to abundant quantities of dense or vacuolated cytoplasm; the term *luteinized granulosa cell tumor* is appropriate when such cells predominate (27). The cells in GCTs usually have round to oval, pale, and often grooved nuclei (Fig. 26.2), but rarely the cells are spindle shaped, resembling a cellular fibroma or low-grade fibrosarcoma; mitotic figures may be numerous, but are rarely atypical. There is usually only mild nuclear atypia, but approximately 2% of tumors contain mononucleate and multinucleate cells with large, bizarre, hyperchromatic nuclei, the presence of which does not appear to worsen the prognosis (32).

Natural History

Adult granulosa cell tumors are low-grade malignancies with a propensity to remain localized and demonstrate indolent growth. Ninety percent are stage I at diagnosis (26). The 10-year survival rate for stage I disease ranges from 86% to 96%; for more advanced disease at diagnosis, 26% to 49% (26). Bilaterality occurs in less than 10% (23). Tumor rupture occurred in 22% of a series of 97 cases (23). A unique feature of GCTs is recurrences at extended time intervals from primary therapy, suggesting the presence of persistent occult disease with a very indolent growth rate. For patients who recur, the median time to recurrence is 6 years and median survival after recurrence is 5.6 years (4,13). Numerous reports exist of recurrences occurring more than a decade following primary treatment (33,34).

Prognostic Factors

The staging system for GCTs is the same as that used for epithelial ovarian cancer (International Federation of Gynecology and Obstetrics [FIGO]). Whereas surgical stage has been recognized as the most important prognostic factor for GCTs, the impact of tumor size, rupture, histologic subtype, nuclear atypia, and mitotic activity on outcome is less clear and larger,

well-characterized series are necessary to clarify existing discrepancies (8,35,36). As noted above, GCTs are large and therefore prone to rupture. Rupture appears to adversely impact survival in stage I patients, justifying stratification as stage IC (13). However, the prognostic importance of positive cytology and surface involvement is less defined in stage I GCTs (8). In a series of 176 GCTs, only residual tumor after surgery (a surrogate for stage) and tumor size >13.5 cm were associated with recurrence on multivariate analysis (37). In other reports, tumor size lost independent predictability when stratified by stage (5,14,18,20,37). Increasing degrees of nuclear atypia and increasing mitotic frequency per 10 high-power fields (HPFs) have been correlated inversely with prognosis. Specimens from patients with more advanced disease tend to demonstrate higher grade of atypia and/or more mitotic figures (5,13,14,18). Despite its somewhat subjective assessment, nuclear grade has been reported to be a reliable prognostic indicator in stage I cases (13,18). The significance of histologic subtypes and ploidy status has been debated, and they appear to be of minimal value. Several investigative groups (4,5,12–14,18) have failed to confirm Kottmeier's (38) report of the prognostic importance of histologic patterns alone in GCTs. Similarly, the results of investigations utilizing flow cytometric analysis of DNA content have been inconsistent. Klemi et al. (39) reported a significant survival advantage for patients with tumors demonstrating normal ploidy and/or an S-phase fraction of less than 6%. However, other investigators have suggested that nondiploid GCTs are infrequently encountered (40,41). Chadha et al. (40) reported that 3 of 5 aneuploid tumors from a total population of 43 pathologically diagnosed GCTs were vimentin negative but positive for cytokeratin and epithelial membrane antigen, and therefore cautioned that such highly aneuploid tumors may represent undifferentiated carcinomas. Indeed, it is clear that some series of GCTs in the literature include undifferentiated carcinomas not otherwise specified, or recently recognized entities such as the large-cell carcinoma of hypercalcemic type. Therefore, series with unusually large numbers of late-stage or poor-prognosis cases should be evaluated cautiously.

Investigators have analyzed several potential molecular markers, including p53 status, telomerase, Ki-67, c-myc, HER2/neu, and VEGF in GCTs (42–47). To date, no molecular marker provides prognostic information for GCTs beyond what is known from stage and histopathologic parameters.

Ala-Fossi et al. stained 30 GCTs for the inhibin subunit. All 24 stage I and II tumors were positive, whereas 4 of 6 stage II–IV tumors were negative. Those that were negative were poorly differentiated and exhibited rapid disease progression. Whether other observers would have accepted these tumors as valid GCTs is a concern. Stage was the sole independent prognostic factor (48).

Serum Markers

Recognizing that the majority of patients presenting with advanced GCTs will recur, the identification of a specific serum tumor marker(s) would facilitate early detection of recurrent disease and monitoring of treatment effectiveness (4,5,16,18). As noted above, serum estrogens are generally produced by GCTs and have been utilized as an indicator of disease status (49). Unfortunately, serum estradiol levels are occasionally normal, and more frequently are only marginally increased, making them less than ideal for monitoring in a significant number of patients. Several proteins derived from granulosa cells, including inhibin, follicle-regulating protein, and müllerian-inhibiting substance, are readily assayable in serum and forwarded as useful diagnostic monitoring markers (50–58). In a prospective evaluation of 27 patients with GCTs, Jobling et al. (52) demonstrated that serum inhibin levels are typically elevated sevenfold above normal follicular phase levels prior to primary

surgical management. Mom et al. showed that inhibin B was the predominant form of inhibin secreted by these tumors, with a sensitivity and specificity of 89% and 100% compared to 67% and 100% for inhibin A. Elevations in inhibin B were present in 85% of recurrences and predated clinical evidence of recurrence by a median of 11 months (59). In recent years, inhibin and calretinin have become useful immunohistochemical markers to assist in the diagnosis of GCTs and, for that matter, other SCSTs (60).

Granulosa Cell Tumors: Juvenile Type

Ovarian neoplasms are relatively rare in childhood and adolescence. When encountered, the majority are of germ cell origin, with only 5% to 7% being SCSTs. The latter, consisting predominantly of the granulosa cell type in this age group, demonstrates a distinct tumor biology from the typical granulosa cell tumor (AGCT) considered above (61). Approximately 90% of the GCTs diagnosed in prepubertal girls and in most women less than 30 years of age will be of the juvenile type (JGCT). In a clinicopathologic analysis of 125 cases of JGCT, 44% occurred prior to age 10 years and only 3% after the third decade of life (62). The majority of prepubertal patients present with clinical evidence of isosexual precocious pseudopuberty, which may include breast enlargement, development of pubic hair, increased vaginal secretions, advanced somatic development, and other secondary sex characteristics (62–66). Serum estradiol levels were reported as being elevated in 17 of 17 cases of JGCTs with pseudopuberty (64). In addition, elevated levels of serum progesterone (6 of 10) and testosterone (6 of 8) were likewise observed, as well as suppressed levels of luteinizing hormone and follicle-stimulating hormone. The occasional patient will harbor an androgen-secreting JGCT accompanied by virilization (62,64,65). Although the signs of either precocious pseudopuberty or virilization are dramatic, the most consistent clinical sign at presentation in patients with JGCTs is increasing abdominal girth. Young et al. (62) indicated that in only 2 of 113 nonpregnant patients with JGCTs was the treating physician unable to palpate a mass on abdominal, pelvic, and/or rectal examination. Abdominal pain, dysuria, and constipation may coexist. Infrequently, a surgical emergency is encountered following spontaneous rupture or torsion of the enlarged ovary. Juvenile granulosa cell tumors may occur in infants, who appear to have a more favorable prognosis than older individuals (67). Hasiakos et al. described a recent case of JGCT associated with pregnancy and reviewed the literature (68).

The frequency of bilaterality for JGCTs is estimated to be 5%, similar to AGCTs (69). When stage was assigned based on surgical and histologic parameters, 88% were stage IA, 2% stage IB, 8% stage IC, and 3% stage II. As noted, extraovarian spread is infrequently encountered at exploration, whereas rupture of the tumor is noted in approximately 10% of cases. Ascites contributes to the abdominal distention in 10% to 36% of cases (62,64).

JGCTs have been reported in association with enchondromatosis alone (Ollier's disease) or concomitantly with hemangiomas (Maffucci's syndrome) (64,70–72). Individuals with these relatively uncommon mesodermal dysplasias generally present prior to puberty and frequently develop secondary neoplasms, most commonly sarcomas, after the second decade of life. Juvenile granulosa cell tumors are the next most frequent tumor associated with these disorders and become evident during the first and second decades of life. These observations appear to imply more than coincidental occurrences and suggest a generalized mesodermal dysplasia, perhaps contributing to the pathogenesis of these neoplastic processes. In addition, congenital bilateral JGCTs of the ovary have been reported in leprechaunism, a disease characterized by insulin resistance resulting from an insulin-receptor defect (73).

Pathology

The appearances of JGCTs are similar to the adult form; a solid and cystic neoplasm, in which the cysts contain hemorrhagic fluid, is common (62,63,66). Uniformly solid and uniformly cystic neoplasms are also encountered; the latter may be multilocular or, in rare instances, unilocular. The solid component is typically yellow-tan or gray and occasionally exhibits extensive necrosis, hemorrhage, or both.

Microscopic examination typically reveals a predominantly solid cellular tumor with focal follicle formation, but occasionally, a uniformly solid or a uniformly follicular pattern is seen. In the solid areas, the neoplastic cells may be arranged diffusely or as multiple nodules of various sizes. The follicles typically vary in size and shape; Call-Exner bodies are rarely encountered, and the follicles rarely reach the large size of those in the macrofollicular AGCT. The follicular lumens in the juvenile tumor contain eosinophilic or basophilic fluid, which stains with mucicarmine in approximately 2 of 3 cases.

The 2 characteristic cytologic features of the neoplastic juvenile granulosa cells that distinguish them from those of AGCT are their generally rounded, hyperchromatic nuclei, which almost always lack grooves, and their almost invariable moderate to abundant eosinophilic or vacuolated (luteinized) cytoplasm (Fig. 26.3). Nuclear atypia in JGCTs varies from minimal to marked; in approximately 13% of the cases, severe degrees are present. The mitotic rate also varies greatly but is generally higher than that seen in AGCTs, often being 5 or more per HPF (62,63).

Natural History

In the initial series by Young et al., 98% of 125 patients with JGCTs were less than 35 years of age, and 78% were 20 years or less (62). Notwithstanding the customary presenting complaint of increased abdominal girth and the clinical documentation of a large mass (64% >10 cm), 90% of the JGCTs analyzed by Young et al. (62) were stage IA or IB. The corresponding survival rate for these patients with an average follow-up of 3.5 years was 97%. Included were 9 stage IA2 patients with rupture of the tumor, all of whom were alive and free of disease. Patients presenting with associated isosexual pseudoprecocious puberty may have a more favorable prognosis. Assessing 80 such cases from 212 reported JGCTs, only 2 cancer-related deaths (2.5%)

FIGURE 26.3. Granulosa cell tumor; juvenile type. A nodule of tumor is composed of large cells with abundant cytoplasm and slightly pleomorphic, hyperchromatic nuclei.

were observed. Presumably, the clinical manifestations lead to early diagnosis and excellent outcomes (62,64–66).

Although the presentation of early symptoms and localized disease are similar to AGCTs, the natural history of JGCTs differs notably in several respects. Although the adult form frequently includes a latency period with recurrences remote from initial diagnosis, the juvenile counterpart is characteristically aggressive in advanced stages and the time to relapse of limited duration, generally within 3 years of initial diagnosis (62,64,66). Thirteen cases of stage II, III, or IV disease were abstracted from 3 analyses with a combined sample size of 180 patients (62,64,65). Of these 13 cases, only 3 patients (23%) were alive when reported, and notably, the recurrences and deaths occurred within a relatively brief interval.

Prognostic Factors

Young et al. (62) noted surgical stage to represent the most reliable prognostic indicator. Tumor size, mitotic activity, and nuclear atypia were significant predictors only when analyzed without regard to stage. In that series, rupture did not correlate with outcome. Schneider et al. reported on a group of 54 SCSTs in children and adolescents from Germany (45 JGCTs and 9 others) (74). They addressed the outcome of patients with “accidental” stage IC disease, defined as violation of the tumor capsule during surgery, versus “natural” stage IC tumors, with preoperative rupture or malignant ascites. Among 12 patients with accidental stage IC disease, there were no recurrences. In contrast, 5 of the 9 patients with natural stage IC disease recurred ($p = 0.001$). Assessment of DNA content via flow cytometry in JGCTs demonstrated nondiploid patterns in nearly half (75,76). However, Jacoby et al. (75) were unable to correlate DNA ploidy or S-phase fraction (SPF) with either stage of disease or prognosis in patients with localized disease. In the series by Schneider et al., mitotic activity correlated with prognosis (74). There were no relapses in 35 patients whose tumors exhibited low or moderate mitotic activity. Among those with high mitotic activity (>19 mitoses per 10 HPFs), approximately half recurred.

Serum Markers

Although information specific to juvenile granulosa cell tumors is limited, the various tumor markers discussed above for AGCTs would appear to be applicable to JGCTs for monitoring of recurrent disease.

TUMORS IN THE THECOMA-FIBROMA GROUP

Considering that the ovarian stromal cell is the precursor of both fibroblasts and theca cells, pure thecomas and pure fibromas appear to represent extremes in a continuum, with a significant percentage of the tumors having admixtures of lipid-laden, steroid-secreting cells and collagen-producing spindle cells. Nonetheless, the vast majority of tumors in the thecoma-fibroma group are readily subcategorized based on relatively distinct clinical and histologic characteristics. The major subcategories include thecoma, fibroma-fibrosarcoma, and the sclerosing stromal cell tumor (SST).

Thecoma

Theca cell tumors (TCTs), or thecomas (Fig. 26.4), are composed of lipid-laden stromal cells, occasionally demonstrating luteinization, and are almost invariably clinically benign (4,77,78).

FIGURE 26.4. Thecoma. The tumor is composed of a mass of clear, vacuolated cells with round to oval nuclei intersected by bands of fibromatous tissue.

Source: Reprinted with permission from Morris JM, Scully RE. *Endocrine Pathology of the Ovary*. St. Louis, MO: Mosby, 1958.

Thecomas account for approximately 1% of ovarian neoplasms and occur at a more advanced age than other SCSTs. The majority of patients are in their sixth and seventh decades at the time of diagnosis (4,77). Combining 2 large series totaling over 140 patients, less than 10% presented prior to age 30 years. Notably, the luteinized tumors are an exception to this generalization, with 30% occurring in women before their fourth decade of life (79). Assessing a compendium of nearly 300 cases, bilaterality occurs with a frequency of approximately 2% and extraovarian spread occurs rarely, if at all (4,77,78,80).

The primary presenting signs and symptoms in patients with TCTs are abnormal vaginal bleeding and/or an abdominal/pelvic mass (77,78,80). The former urges initiation of medical intervention in the majority of postmenopausal patients, whereas an increasing abdominal girth or a palpable mass is more frequently the main presenting complaint of premenopausal patients. Lesion size has been reported to vary from less than 1 to 40 cm in diameter (77,78,80). Ascites is occasionally encountered.

Thecomas are considered to be among the most hormonally active of the SCSTs. The abnormal bleeding encountered in 60% of patients is presumably attributable to excess estrogen production (77,78). In the series reported by Evans et al. (4), endometrial hyperplasia was observed in 37% of the evaluable patients, and adenocarcinoma consistent with an unopposed estrogen effect was documented in an additional 27%. All the uterine cancers were well differentiated and minimally invasive, but 2 patients subsequently died of endometrial carcinoma. Other coexisting uterine pathologic findings potentially influenced by elevated circulating estrogen levels included leiomyomata, myohypertrophy, and endometrial polyps. Conversely, Zhang et al. (79) noted that nearly one-half of the evaluated luteinized thecomas were either nonfunctional or androgenic, resulting in a relatively significant frequency of masculinization.

An enigmatic tumor that has been considered to be a variant of luteinized thecoma has been associated with sclerosing peritonitis (81). These tumors are often bilateral and frequently have a brisk mitotic rate, but have not been shown to have metastatic potential. Sclerosing peritonitis has, however, been fatal owing to complications pursuant to it. Schonman et al. present a case of luteinized thecoma associated with sclerosing peritonitis treated with ovarian wedge resection (82). Despite a recurrent bowel obstruction, she was successfully treated with high-dose

steroids. She achieved pregnancy and was free of symptoms 18 months following treatment.

Fibroma-Fibrosarcoma

Fibromas represent the most commonly encountered SCST, accounting for approximately 4% of all ovarian neoplasms. These endocrine-inert tumors are seldom bilateral and vary in size from microscopic to extremely large masses. Although infrequently diagnosed prior to age 30 years, fibromas can occur at any age; the average age of diagnosis is the latter half of the fifth decade of life (83). As their size increases, fibromas tend to become more edematous, leading to the escape of increasing quantities of fluid from the tumor surfaces. Ascites is detected in association with 10%–15% of ovarian fibromas exceeding a diameter of 10 cm (84). Furthermore, 1% of patients develop a hydrothorax in addition to the hydroperitoneum (Meigs' syndrome) (85). Gorlin's syndrome represents an inherited predisposition to the development of ovarian fibromas along with several other abnormalities, the most frequent of which is the appearance of basal-cell nevi at an early age (86).

Although ovarian fibromas are generally benign, approximately 10% will demonstrate increased cellularity and varying degrees of pleomorphism and mitotic activity. Fibromatous tumors characterized histologically by an increased cellular density and brisk mitotic activity are designated cellular fibromas and are considered to be tumors of low malignant potential, particularly if ruptured or associated with adhesions (87). In contrast, fibrosarcomas are highly malignant neoplasms. These tumors are distinguished by their greater cellular density and, most notably, moderate to marked pleomorphism (88).

Sclerosing Stromal Cell Tumors

SSTs were initially described by Chalvardjian and Scully (89) in 1973 as a distinct subgroup within the thecoma-fibroma family of ovarian tumors. Accounting for less than 5% of SCSTs, this relatively rare tumor characteristically differentiates itself histologically and clinically from both thecomas and fibromas (90,91). Histologically, the presence of pseudolobulation of cellular areas separated by edematous connective tissue, increased vascularity, and prominent areas of sclerosis are distinguishing features. Clinically, SSTs commonly become manifest during the second and third decades of life, with 80% being diagnosed prior to age 30 years, which is unique among ovarian stromal tumors (92). The signs and symptoms that most commonly necessitate medical evaluation include menstrual irregularities and/or pelvic pain (93). Despite the relatively large tumor size, which ranges from clinically undetectable to 20 cm or more in greatest diameter, ascites is seldom encountered; this further contrasts SSTs from fibromas (93). In contrast to thecomas, SSTs were originally considered to be inactive endocrinologically (89). However, a limited number of cases have been subsequently reported in which steroidogenic activity has been clinically demonstrable (93–96). To date, all SSTs have been clinically benign, and with one exception (97), all have been unilateral. Although a recent report noted an elevated CA-125 level, which the investigators speculated was perhaps nonspecific (98), no specific tumor marker has been identified for SSTs to date.

Natural History

Ovarian thecomas, fibromas, and SSTs are considered to be benign neoplasms, and any associated morbidity or mortality is attributable to the treatment modalities or the sequelae of concurrent disease (4,77,80,83,99). Examples of the latter are deaths from endometrial carcinoma resulting from the unopposed estrogen produced by the thecomas (4). Although several

cases of "malignant thecomas" have been reported, critical reappraisal of such tumors invariably results in histologic reassignment to sarcomas or diffuse granulosa cell tumors (100). DNA ploidy analyses of thecomas and fibromas demonstrate aneuploid patterns in the majority, most commonly trisomy and/or tetrasomy 12, which offer a clue to their pathogenesis (101,102).

Prognostic Factors

The prognosis for patients diagnosed with cellular fibromas is generally considered to be quite favorable. Recurrences of these tumors of low malignant potential are generally correlated with adherent disease, rupture, or incomplete removal at the time of primary cytoreduction (87). Fibrosarcomas are associated with an extremely poor prognosis, but fortunately they are rare.

SERTOLI STROMAL CELL TUMORS

Neoplasms arising in the ovary exhibiting morphologic characteristics similar to those of the testes during various stages of gonadogenesis were recognized and elegantly described by Meyer (103,104). He reasoned that the origin of these tumors was the male blastema and coined the term *arrhenoblastoma*. Considering the functional nature of these male homologs and the varying degrees of associated defeminization and/or masculinization, the term *androblastoma* was also adopted. However, Morris and Scully (105), in 1958, contended that both designations implied masculinization, which is frequently absent, and furthermore facilitated the inclusion of a variety of unrelated androgen-producing ovarian tumors. Therefore, they recommended the adoption of the morphologic designation Sertoli-Leydig cell tumor (SLCT), which also allowed a consistent nomenclature for the general classification of SCSTs of the ovary. The SLCTs include tumors composed of Sertoli cells only, Leydig cells only, and a combination of Sertoli and Leydig cells.

Sertoli Cell Tumors

Sertoli cell tumors are rare, accounting for less than 5% of all SLCTs (92). The average age at presentation is about 30 years, but this lesion can occur at any age. Evidence of estrogen production has been observed in approximately two-thirds of the reported cases. Consistent with excess estrogen production, isosexual precocious puberty has been witnessed during the first decade of life, menstrual disorders during the reproductive decades, and postmenopausal bleeding in the decades after the climacteric. Reflecting tumor size (average 9 cm), capsular distention, and/or adnexal torsion, and abdominal distention and/or pain are frequent complaints. Pelvic examination generally confirms the presence of the tumor under these circumstances. The frequency with which excessive renin production has been associated with Sertoli cells appears to exceed mere chance (106–108). Evaluation of refractory hypertension and hypokalemia has rarely eventuated in the discovery of a Sertoli cell tumor as the origin of the excess renin. An occasional Sertoli cell tumor has arisen in a patient with the Peutz-Jeghers syndrome (PJS) (109).

Pathology

On gross examination, these rare tumors are typically solid, lobulated, and yellow (92,110). Microscopic examination typically shows hollow or solid tubules lined by cells that usually have relatively bland cytologic features, but rare tumors exhibit moderate to severe nuclear atypia. In most tumors, a tubular pattern predominates, but occasionally a diffuse pattern is conspicuous.

Prognosis

The great majority of these rare tumors have been unilateral stage I lesions. The greater majority of Sertoli cell tumors are well differentiated, and only rare tumors are malignant (92). Excision of the tumor results in prompt resolution of the hyperestrogenic state. (Leydig cell tumors are discussed in the section on steroid cell tumors below.)

Sertoli-Leydig Cell Tumors

SLCTs are extremely uncommon, accounting for less than 0.2% of all ovarian tumors. As implied by their designation, the tumors contain both Sertoli and Leydig cell elements. Many of the clinical characteristics are related to the degree of histologic differentiation and the presence of a retiform pattern and/or heterologous elements (described below). The average patient age at diagnosis is approximately 25 years, with the majority (70%–75%) of the tumors becoming clinically manifest during the second and third decades of life. Less than 10% occur either prior to menarche or after the climacterium. Patients harboring well-differentiated tumors present at an average age of 35 years, or 10 years later than patients with intermediate or poorly differentiated lesions. Conversely, tumors with retiform patterns are generally detected 10 years earlier than the intermediate and poorly differentiated tumors (111–113). Based on the compiled data from 3 reported series totaling over 300 patients, the frequency of extraovarian spread of disease at the time of diagnosis is approximately 2% to 3%. In addition, the likelihood of encountering bilateral tumors is even less frequent (111–113).

The most frequent complaints at the time of presentation of these generally healthy adolescents and young adults are menstrual disorders, virilization, and nonspecific symptoms resulting from an abdominal mass. Nearly one-half of the patients experience sufficient abdominal pain or discomfort or note abdominal distention or palpate a mass on self-examination to prompt professional assessment. Whereas capsular distention and/or intralesional hemorrhage or necrosis of the tumor and/or adjacent visceral compression by the tumor account for the associated chronic or intermittent pain, acute abdominal pain necessitating emergency intervention invariably reflects vascular compromise from torsion. While lesion size varies according to histologic differentiation (approximately 5 cm for well-differentiated tumors to >15 cm for poorly differentiated tumors), abdominal, vaginal, and/or rectal examination readily identifies an adnexal mass in approximately 95% of symptomatic patients. The most common premonitory symptoms, namely, menstrual disorders and subtle androgenic manifestations, predate by several months, and less often, by years, the recognition of the overt clinical signs or symptoms. Irregular bleeding, oligomenorrhea, and postmenopausal bleeding, retrospectively, have been attributed to either excess androgens or estrogens. The etiology of the latter is presumably the peripheral conversion of androgens to estrogens or, rarely, from an estrogen-secreting SLCT. Frank virilization occurs in 35% of the patients with SLCTs, and another 10% to 15% have some clinical manifestations consistent with androgen excess. The most frequent androgenic symptom complex encountered includes amenorrhea, voice deepening, and hirsutism. In addition, breast atrophy, clitorimegaly, loss of female contour, and temporal hair recession, for example, are signs of masculinization witnessed in patients with SLCTs (111–113). The prevalence of androgenic manifestations appears to be independent of the degree of histologic differentiation, but is observed less frequently in heterologous SLCTs and only occasionally in patients harboring retiform lesions (112,114–117). Although the preoperative diagnosis of SLCT in the absence of androgenic excess may be impossible, this neoplastic entity should constitute the primary preoperative diagnosis in patients with androgenic manifestations presenting

during the second through the fourth decades of life with a unilaterally palpable adnexal mass.

Uncommonly, estrogen manifestations are witnessed in the context of presumed end-organ estrogenic responses, including postmenopausal bleeding and endometrial polyp formation, hyperplasia, and adenocarcinoma. Cautious interpretation of such observations is required, realizing that peripheral conversion of androgens to estrogens may be as plausible as a primary estrogen-secreting SLCT. As expected from the clinical findings, most patients demonstrating signs of defeminization or virilization have elevated plasma testosterone levels (111–113). Whereas plasma androstenedione may occasionally be elevated, the urinary 17-ketosteroids, including dehydroepiandrosterone, are usually normal, with the occasional patient presenting with a slightly elevated level. An elevated testosterone/androstenedione ratio generally suggests the presence of an androgen-secreting ovarian tumor, most likely an SLCT. Recognizing that certain gonadotropin-releasing hormone (GnRH) agonists modulate androgen production by downregulating gonadotropin levels and through a direct effect on the ovary, Pascale et al. (118) demonstrated successful suppression of testosterone and androstenedione in five virilized women with the administration of GnRH agonists. Their data suggest that androgen-secreting tumors of the ovary appear to be less autonomous than such tumors originating in the adrenal gland. Surgical excision of the SLCTs results in a precipitous drop in androgen levels and, over time, partial to complete resolution of the clinical manifestations associated with androgen excess is observed.

The coexistence of other diseases with SLCTs has been chronicled. The frequency with which thyroid disease is observed in these patients appears to exceed mere chance. Furthermore, several cases of other mesenchymal tumors have occurred in patients with SLCTs, including sarcoma botryoides of the cervix as well as Ollier's disease (112,119). The latter is a rare disease, but it is associated with other SCSTs, specifically JGCTs, as noted above. Finally, a tendency toward familial occurrence appears to exist (112).

Pathology

Gross Features

Sertoli-Leydig cell tumors vary in size from small to huge masses, but most are between 5 and 15 cm in diameter. The majority are solid, often yellow, and lobulated (Fig. 26.5), but many are solid and cystic. Pure cystic tumors are exceptionally rare, in contrast to the situation with GCTs. Poorly differentiated tumors tend to be larger than those more differentiated, and contain areas of hemorrhage and necrosis more frequently (112). Tumors with heterologous or retiform components are more often cystic than other tumors in this category (114,115,117,120). The heterologous tumors occasionally simulate mucinous cystic tumors on gross examination, and retiform tumors may contain large edematous intracystic papillae, resembling serous papillary tumors, or may be soft and spongy with varying degrees of cystification (117).

Microscopic Features

Well-differentiated SLCTs are characterized by a predominantly tubular pattern (121). On low-power examination, a nodular architecture is often conspicuous, with fibrous bands intersecting lobules composed of small, round, hollow, or, less often, solid tubules lined by well-differentiated cells and separated by variable numbers of Leydig cells. Rarely the tubules appear pseudoendometrioid (122).

Sertoli-Leydig cell tumors of intermediate and poor differentiation form a continuum characterized by a variety of patterns and combinations of cell types (111–113). Some tumors exhibit intermediate differentiation in some areas and poor differentiation in others, and less commonly, tumors of intermediate

FIGURE 26.5. Sertoli-Leydig cell tumor. The sectioned surface of the tumor is focally lobulated and was yellow in the fresh state.

differentiation contain well-differentiated foci. Both the Sertoli cells and the Leydig cells may exhibit varying degrees of immaturity. In tumors of intermediate differentiation, immature Sertoli cells have small, round, oval, or angular nuclei and generally scanty cytoplasm and are arranged typically in ill-defined masses, often creating a lobulated appearance on low power; solid and hollow tubules, nests, broad columns of Sertoli cells, and, most characteristically, thin cords resembling the sex cords of the embryonic testis are often present (Fig. 26.6). These structures are separated by stroma, which ranges from fibromatous to densely cellular to edematous, and typically contains clusters of well-differentiated Leydig cells (Fig. 26.6). Cysts containing eosinophilic secretion may be present and create a thyroid-like appearance, and follicle-like spaces are encountered rarely. The Sertoli cell and Leydig cell elements, singly or in combination, may contain varying and sometimes large amounts of lipid in the form of small or large droplets. When a significant amount of the stromal component is made up of immature cellular mesenchymal tissue with high mitotic activity resembling a nonspecific sarcoma, the tumor is poorly differentiated.

Fifteen percent of SLCTs have a substantial retiform component, and are so designated because they are composed of a network of elongated tubules and cysts, both of which may contain papillae, resembling the rete testis (32). This pattern is usually accompanied by other patterns of SLCTs, but sometimes an entire tumor has a retiform pattern.

Heterologous elements occur in approximately 20% of Sertoli cell tumors (118,123). In a series of these tumors, 18% contain glands and cysts lined by moderately to well-differentiated intestinal-type epithelium (118). Mesenchymal heterologous elements, encountered in 5% of Sertoli cell tumors, include islands of cartilage arising on a sarcomatous background, areas of embryonal rhabdomyosarcoma, or both (123).

Natural History

SLCTs display characteristics that differ markedly from their epithelial counterparts, notably in regard to their malignant potential. Despite an average size of approximately 16 cm, only

FIGURE 26.6. Sertoli-Leydig cell tumor; intermediate differentiation. Nests of large Leydig cells (arrow) lie among bands of immature Sertoli cells.

2% to 3% of SLCTs have demonstrable extraovarian spread at the time of detection. Furthermore, Young et al. (62) identified only 29 clinically malignant cases in their series of 220 SLCTs having variable observation intervals, and they noted an 18% malignancy rate among 164 patients with adequate follow-up. At least in part, the more favorable prognosis reflects the abrupt onset of androgenic manifestations and the early detection of nonspecific symptoms, which promote prompt medical assessment. Nevertheless, the natural history of the malignant variant includes early recurrences, with approximately two-thirds becoming evident within 1 year of treatment and only 6%–7% recurring after 5 years. The abdominal cavity (including the pelvis) and the retroperitoneal nodes are the most frequent sites for recurrences. In addition, the contralateral ovary, lungs, liver, and bone are other reported sites of recurrent metastatic disease. The collective salvage rates in patients with clinically malignant disease are low, with extrapolated estimates being less than 20%.

Prognostic Factors

Stage is the most important predictor of outcome in SLCTs. Fortunately, 97% of SLCTs are reportedly stage I at diagnosis, and less than 20% of these localized tumors become clinically malignant. The most cogent phenotypic prognostic determinant for stage I SLCTs is the degree of histologic differentiation (111–113). Approximately one-half of the reported SLCTs are of intermediate differentiation, 10% are well differentiated, 20% are heterologous, and the remainder are poorly differentiated. No extraovarian spread or subsequent recurrences were encountered by Young and Scully (121) among 23 well-differentiated SLCTs. However, approximately 10% of intermediate and 60% of poorly differentiated tumors, as well as 20% of heterologous tumors, demonstrated clinically malignant behavior (112). The heterologous tumors contain either endodermal elements such as gastrointestinal epithelium and carcinoids or mesenchymal elements including skeletal muscles and/or cartilage. The endodermal elements are typically associated with intermediately differentiated homologous elements and represent 75% of the heterologous SLCTs. Their corresponding prognosis parallels that of the intermediately differentiated homologous tumors. In contrast, heterologous tumors containing mesenchymal elements account for 5% of all SLCTs and invariably coexist with a poorly differentiated homologous component. The clinically aggressive malignant behavior of poorly differentiated heterologous tumors is witnessed in the extremely low survival (112).

Retiform patterns, tumor size, mitotic activity, and tumor rupture appear to increase in frequency as the degree of tumor differentiation decreases (111–113). Approximately 10% of neoplasms express histologic patterns resembling the rete testis. They are more commonly observed in younger patients (average age, 15 years) and are generally larger, possibly secondary to the less frequent association of androgenic manifestations and hence a later clinical presentation (114–117). Sertoli-Leydig cell tumors harboring a retiform pattern are associated with a 20% malignancy rate, significantly higher than the 12% non-retiform SLCT rate. Young and Scully (117) noted that 14 of 25 retiform cases were of intermediate differentiation, with 1 demonstrating poorly differentiated homologous histology and 10 exhibiting heterologous elements (3 intermediate and 7 poorly differentiated). Arguably, the less favorable prognosis reflects the frequency of associated heterologous and/or poorly differentiated homologous lesions. This concept is supported by the findings that the majority of the metastatic lesions do not contain retiform patterns (117). However, the adverse characteristics of the retiform component are witnessed when examining tumors of intermediate differentiation. Although only 4 of over 100 reported intermediately differentiated SLCTs were clinically malignant, 3 of the 4 contained retiform patterns (112).

Tumor size, mitotic activity, and tumor rupture have been reported to influence prognosis (111,112). The size, mitotic index, and rupture frequency appear to increase as histologic dedifferentiation increases. Notwithstanding these associations, substratification of intermediate and poorly differentiated lesions according to these parameters identifies significant prognostic differences.

The frequency of androgen excess has been addressed above, with 50% or more of patients diagnosed with SLCTs either directly or indirectly displaying clinical manifestations of hyperandrogenism. Serum testosterone levels are invariably elevated when virilization is present, and selective venous catheterization has documented the ovary as the site of origin (124,125). In addition, immunostaining was positive for testosterone in eight SLCTs analyzed, including a limited number of tumors from patients without clinical signs or symptoms of androgen excess (2,126). The Leydig cells, as anticipated, were shown to be the cell of origin for the synthesis of testosterone. Following cytoreductive surgery, the serum testosterone levels are rapidly cleared from the circulation and have been reported on occasion to increase again as a function of the burden of recurrent metastatic disease.

Other unique secretory products, namely, inhibin and alpha fetoprotein (AFP), have been reported in a limited number of SLCTs and are proteins generally equated with GCTs and germ cell tumors, respectively (115,117,125–127). In addition to GCTs, the Sertoli and Leydig cells have been shown to produce inhibin in testicular tissues, and presumably these same cell types are the site of origin in the SLCTs. Motoyama et al. (127) summarized the literature and reported the 14th case of an elevated serum AFP accompanying SLCTs. A clinically malignant course was appreciated in 43% of the described population, which had a mean age of 16 years. In addition, the majority (57%) was described as having a retiform component, a frequency substantially higher than the 10% usually seen in larger SLCT samples. Perhaps preferential AFP sampling accounts for a portion of this seemingly unusually high frequency in that, histologically, the retiform pattern may be confused with an endodermal sinus tumor, particularly in the absence of clinical androgenic manifestations. The Sertoli and Leydig cells appear to be the cells of origin for AFP within the tumor. Employing immunostaining, Gagnon et al. (126) confirmed that Leydig cells appear to be the predominant site for AFP synthesis, but Sertoli cells are also capable of producing this oncoprotein. Testing 4 retiform and 4 nonretiform SLCTs, they demonstrated a 50% positivity rate in both histologic subtypes. The precise frequency of both inhibin

and AFP positivity and their correlation with disease activity await larger confirmatory assessments.

OVARIAN SEX-CORD TUMOR WITH ANNULAR TUBULES

In 1970, Scully (69) described a limited series of unique ovarian tumors characterized by either simple or complex ring-shaped tubules and proposed the morphologic designation ovarian sex cord tumor with annular tubules (SCTATs). The distinctive cellular elements of these neoplasms were judged to be histologically representative of an intermediate between Sertoli cell and GCTs. Shen et al. (128) reported that SCTATs accounted for 6% of the sex-cord tumors treated at their institution. An association with PJS was likewise recognized, and in a subsequent report of 74 cases of SCTAT, Young et al. (129) noted that approximately 1 in 3 SCTATs occurred in patients with PJS. Ovarian sex cord tumors with annular tubules occurring in association with PJS are typically small (many microscopic), multifocal, calcified, and bilateral. The average age of presentation is the early to mid-portion of the fourth decade of life (129,130). The non-PJS tumors are considerably larger, seldom multifocal or calcified, and invariably unilateral. The average age of these patients is the mid to latter portion of the third decade of life.

Abnormal vaginal bleeding is the most common presenting complaint, including menstrual irregularities during the reproductive era and postmenopausal bleeding during the mature years. Menometrorrhagia followed by prolonged episodes of amenorrhea is commonly experienced in the non-PJS patients. Abdominal pain or discomfort is less frequently encountered, but generally accompanies grossly involved adnexa or other incidental pelvic pathology. In addition, the signs and symptoms accompanying intussusception secondary to colonic polyp formation may be manifested in PJS-associated patients. The majority of PJS-associated SCTATs are not detectable via clinical examination and are appreciated unexpectedly during surgical or pathologic assessment. In contrast, the majority of non-PJS SCTATs are palpable on abdominal and/or vaginal examination. Although these tumors are seldom encountered during the first decade of life, isosexual precocity is invariably witnessed when SCTATs are diagnosed in affected children (129–132).

Considering the rarity of both PJS, an autosomal dominant disorder, and SCTAT, the frequency of concurrency of these two processes suggests a potential linkage in their pathogenesis. Approximately 36% of SCTATs are observed in patients with PJS. In addition, 15% of PJS-associated SCTATs also develop adenoma malignum of the cervix (AMC), a neoplasm that defies early diagnosis and is associated with a relatively high mortality rate (129,133–135). A recent report of 34 patients with PJS demonstrated a significantly elevated risk (relative risk = 20.3) of breast and gynecologic malignancies in women (136); 1 patient had a Sertoli-Leydig tumor and 3 had sex cord tumors with annular tubules. The PJS gene was mapped to chromosome 19p13.3 (137) and was later identified as a novel serine threonine kinase, STK11 (138). Because of the wide variety of malignancies occurring in individuals with PJS, STK11 is believed to function as a general tumor-suppressor gene.

Contingent on the patient's age, precocious puberty, menstrual irregularities, or postmenopausal bleeding are clinical manifestations of SCTATs, indirectly attesting to their endocrine activity (129–133,135,139,140). These signs of hyperestrogenism and the corresponding effects on the endometrium were readily recognized in the initial description of these unique tumors (61). Numerous reports have confirmed the presence of endometrial hyperplasia and/or polyp formation, particularly in PJS-associated SCTATs. Although similar signs in endometrial

histology can be observed in non-PJS SCTATs, clinical histories of menorrhagia followed by episodes of amenorrhea are more frequently obtained (128–131,139,140). Endometrial sampling in a limited population of such patients has demonstrated a spectrum from atrophic glandular to secretory or decidualized endometrium suggestive of significant levels of progesterone production (128,130,140). Assessment of circulating steroid levels has confirmed the presence of excessive estrogen in essentially all SCTAT cases (128,139–141). However, normal progesterone levels have been observed in PJS-associated tumors, but elevated quantities of progesterone have been documented in non-PJS patients (128,139–141). Shen et al. (128) demonstrated elevated estrogen and progesterone levels (and normal testosterone levels) in 2 SCTAT patients without PJS having documented glandular atrophy and decidual stromal changes. Utilizing selective ovarian venous sampling, Crain (140) demonstrated a significant progesterone gradient between peripheral and ovarian venous serum in a non-PJS patient with pseudodecidual changes of the endometrium. Complete resolution of the manifestations attributed to these hormonal imbalances has been routinely witnessed with surgical extirpation of the ovarian neoplasm.

Pathology

Grossly, the PJS-associated tumors are solid and yellow. The non-PJS-associated neoplasms may be similar, but in some cases, they are solid and cystic or mostly cystic. This tumor is characterized microscopically by the presence of simple and complex annular tubules (Fig. 26.7). The simple tubules have the shape of a ring, with the nuclei oriented around the periphery and around a central hyalinized body composed of basement membrane material; an intervening anuclear cytoplasmic zone forms the major component of the ring. The more numerous complex tubules are rounded structures made up of intercommunicating rings revolving around multiple hyaline bodies. In patients with PJS, the tumors are typically multifocal and exhibit calcification.

Prognostic Factors

Notwithstanding their histologic similarities, the differences in the natural history and hence long-term prognosis for SCTATs associated with PJS and SCTATs independent of PJS are readily apparent. Those detected in women with PJS are benign.

FIGURE 26.7. Sex-cord tumor with annular tubules. Numerous rounded tubules encircle multiple hyaline bodies.

Important in the management of this entity, however, is the recognition that approximately 15% of these patients will harbor an AMC. In addition, there are almost always exceptions to the rule. Barker et al. reported a 54-year-old woman with SCTAT and PJS who demonstrated aggressive malignant behavior and had multiple recurrences (142). The authors also reviewed the literature, identifying 2 previous such patients. As a result of delayed declaration of symptoms, the diagnosis of AMC is frequently made following examination of the hysterectomy specimen. As evident in the recent review by Srivatsa et al. (135), the prognosis for PJS patients with SCTAT and AMC is ominous, reflecting high AMC recurrence rates and refractoriness to treatment.

Based on the compiled data from 4 reported series totaling 63 patients with SCTATs without clinically apparent PJS, the clinical malignancy rate approximated 20% (128–131). Primary extraovarian extension and/or the recurrence frequency has been correlated with the original tumor size and mitotic activity. The tumor characteristically has a relatively long doubling time, a propensity for lymphatic dissemination, and an aptness to remain lateralized. As the primary ovarian lesion is invariably unilateral, the lymphatic metastases are invariably ipsilateral, extending within the confines from the paraortic region to the supraclavicular area. The nature of the retroperitoneal metastases generally facilitates surgical resection and repeat cytoreduction. The tumor's indolent growth pattern, coupled with the relative ease of resection, affords patients extended palliation.

Because SCTATs possess characteristics of both granulosa cells and Sertoli cells, tumor markers elicited by either or both cell types might find utility in the diagnosis and surveillance of these tumors as well. The observed increased serum estrogen levels and the corresponding clinical manifestations recognized with SCTATs suggest utility in monitoring hormone levels. Unfortunately, serum estradiol lacks adequate sensitivity, particularly when the residual tumor volume is limited. However, recent reports demonstrate the potential value and sensitivity of two unique secretory proteins as tumor markers for SCTATs. Gustafson et al. (141) illustrated the applicability of monitoring serum inhibin and müllerian-inhibiting substance (MIS) in the management of a patient with advanced, recurrent SCTAT. More recently, Puls et al. (143) likewise reported an excellent correlation between serum inhibin and MIS levels and the clinical status of a patient with SCTAT during chemotherapy administration. The ultimate utility of these tumor markers awaits accrual of sufficient numbers of patients with SCTATs to address adequately sensitivity and specificity issues.

SEX CORD-STROMAL TUMORS, UNCLASSIFIED

This ill-defined group of tumors, which accounts for less than 10% of those in the sex cord-stromal category, comprises those in which a predominant pattern of testicular or ovarian differentiation is not clearly recognizable. Talerman et al. (144) have recently segregated from within this category a group of tumors for which they have proposed the designation “diffuse nonlobular androblastoma.” The 6 ovarian tumors they reported were mostly estrogenic and had a predominant diffuse proliferation of cells resembling theca cells, granulosa cells, or both, but 5 of the six cases also contained steroid-type cells and tubules typical of Sertoli cell neoplasia.

SCSTs may be particularly difficult to subclassify when they occur in pregnant patients because of alterations in their usual clinical and pathologic features (145). Their nature is rarely suggested clinically because during pregnancy, estrogenic

manifestations are not recognizable, and androgenic manifestations are rare. In one study, 17% of 36 SCSTs that were removed during pregnancy were placed in the unclassified group, and many of those that were classified in the granulosa cell or Sertoli-Leydig cell category had large areas with an indifferent appearance (145).

Gynandroblastoma

Gynandroblastoma is an extremely rare SCST if strict morphologic criteria are followed to establish the diagnosis. Microscopically, these tumors must demonstrate readily identifiable (at least 10%) granulosa cells and tubules of Sertoli cells. Not surprisingly, the corresponding stromal cells, namely, theca and/or Leydig cells, may also be present in varying degrees. Martin-Jimenez et al. (146) recently reviewed the world literature and were able to identify only 17 authenticated cases of gynandroblastoma. Patients presented at an average age of 29.5 years (range, 16–65 years) with primary symptoms of menstrual disturbances consistent with the predominant functional status of the tumor. Commonly, a hyperandrogenic clinical profile is elicited, but signs and symptoms of excessive estrogens or no endocrine manifestations can be encountered. Amenorrhea, hirsutism, and clitorimegaly are frequently noted in association with elevated testosterone levels. Conversely, the common end-organ responses to hyperestrogenism include menometrorrhagia, postmenopausal bleeding, and endometrial hyperplasia. Although the unilateral masses are typically small, 75% are palpable prior to surgical exploration and are characterized by well-differentiated ovarian and testicular constituent elements. Regardless of the associated hormonal activity, gynandroblastomas are considered to be tumors of low malignant potential. To date, only a single case was reported to have been clinically malignant and resulted in death of the patient (147). A gynandroblastoma in pregnancy has also been reported (148).

Steroid Cell Tumors

Steroid cell tumors (SCTs) constitute only 0.1% of all ovarian neoplasms. The predominant components of these tumors are steroid hormone-secreting cells including lutein cells, Leydig cells, and adrenocortical cells. Until recently, the term *lipid cell tumors* was applied to these neoplasms, but Hayes and Scully (149) noted that 25% of such designated tumors did not contain appreciable intracellular fat. Hence, the functional designation steroid cell tumors was suggested and stratified into 3 subclasses: stromal luteoma, Leydig cell tumor, and steroid cell tumors not otherwise specified. The first 2 categories are essentially invariably benign, but some in the third group are malignant.

Stromal Luteoma

In 1964, Scully et al. (150) described the stromal luteoma as a distinctive type of steroid cell tumor. These relatively small (<3 cm) tumors are localized within the parenchyma of the ovary and account for approximately 25% of SCTs. They are thought to arise from luteinized stromal cells or their precursors. Histologically, the adjacent ovarian matrix as well as the contralateral ovary demonstrate stromal hyperthecosis in the vast majority of cases. The distinction between nodular hyperthecosis and stromal luteomas has been arbitrarily based on size, with lesions <5 mm being referred to as nodular hyperthecosis. In contrast to stromal hyperthecosis, stromal luteomas are rarely bilateral.

The average age at which stromal luteomas are diagnosed is the latter half of the sixth decade of life, with 80% occurring after the climacterium (149). Considering that the predominant

functional profile is estrogenic, the result of either direct tumor secretion or peripheral conversion of androgens, it is not surprising that abnormal vaginal bleeding is the primary complaint. In a series of 25 cases reported by Hayes and Scully (149), information regarding the histologic architecture of the endometrium was known for 17 cases, which included 14 cases of hyperplasia and a single case of a well-differentiated adenocarcinoma of the endometrium. Conversely, 12% of the patients presented with clinical manifestations of hyperandrogenism. In their analysis, 20% of the tumors were functionally quiescent and were detected incidentally during histologic assessment of surgical specimens processed for a variety of other indications.

Prognostic Factors

Considering the small size and lack of atypical histology, the posttreatment course is benign. To date, we are unaware of a single adverse outcome. Any untoward sequelae related to the stromal luteoma would presumably reflect secondary events from prolonged excessive hormone secretions such as an endometrial carcinoma.

Leydig Cell Tumors

Leydig cell tumors account for only 15% to 20% of SCTs. Histologically, the cellular elements are indistinguishable from lutein cells or adrenocortical cells except for the presence of crystals of Reinke, a requirement based on either light or electron microscopy for definitive diagnosis. Roth and Sternberg (151) subdivided these tumors according to location and possibly the cell of origin, namely, Leydig cell tumors of hilar type versus nonhilar type. Whereas the latter presumably arise from ovarian stromal cells and are extremely rare, the former tumors are located in the hilus of the ovary and encroach on or extend into the ovarian stroma in varying degrees. Other tumors containing features of Leydig cell tumors (such as location in the ovarian hilus or adjacent to nonmyelinated nerve fibers, location within a continuum of hilar cell hyperplasia, fibrinoid vascular changes in the tumor, clustering of cells around vessels) but lacking crystals of Reinke are preferably categorized as steroid cell tumors not otherwise specified (152). By combining 2 reviews (152,153) that summarize the English-language literature prior to and after 1966, 38 Reinke-positive cases affording adequate abstraction were identified. These invariably unilateral tumors are typically small, ranging in size from 0.7 to 15 cm, with a mean of 2.7 cm, and are therefore frequently not detectable via clinical examination or pelvic imaging. Similar to stromal luteomas, the age of diagnosis is 58 years (range, 37 to 86 years), with only a small percentage occurring prior to the climacterium. The initial clinical manifestations are usually consistent with a hyperandrogenic state. Overt signs of virilization are observed in greater than 80% of the patients. These include one or more of the following: hirsutism, acne, deepening of the voice, breast atrophy, clitorimegaly, and male-pattern baldness. In contrast to the frequently dramatic onset and progression of virilization witnessed with SLCTs, ovarian Leydig cell tumors are generally characterized by a more indolent course. Paraskevas and Scully (152) reported an interval of 7 years between recognized onset of signs and symptoms of androgen excess and diagnosis. Analysis of serum androgens demonstrated testosterone to be consistently elevated while urinary 17-ketosteroids were normal or marginally increased. These observations suggest minimal production of androstenedione or dehydroepiandrosterone by these tumors.

Conversely, estrogenic manifestations are occasionally witnessed, such as irregular menses or postmenopausal bleeding (152,153). Pathologic assessment of the uterus may reveal endometrial hyperplasia, polyp formation, and/or carcinoma in the presence or absence of leiomyomata and/or myohypertrophy.

Whether the hyperestrogenic features are a result of tumor secretion of estrogens or peripheral conversion of androgens to estrogens remains to be ascertained.

Prognostic Factors

In a review of the English literature through 1988, 38 Reinke-positive cases were accrued and only a single case of a clinically malignant lesion was identified (152,153). Based on tumor size (15 cm) alone, this sole example might be considered to be an outlier. Hence, similar to stromal luteomas, ovarian Leydig cell tumors are essentially benign neoplasms with the primary postsurgical concerns consisting of regression of the androgen-induced alterations. Generally speaking, significant regression is witnessed, but significant residual sequelae are appreciated in approximately one-half of the patients.

Steroid Cell Tumors Not Otherwise Specified

Neoplasms identified as steroid cell tumors but lacking the specific characteristics of stromal luteomas or Leydig cell tumors are collectively classified as steroid cell tumors not otherwise specified (SCTNOS). These tumors constitute the majority of steroid cell tumors and undoubtedly include both Leydig cell tumors and stromal luteomas that fail to meet specific identification criteria already noted. Although serving as a catchment for an undefined percentage of steroid hormone-secreting tumors, as a group, the SCTNOS have nonetheless unique characteristics. The natural history and biology of these tumors are significantly different when compared to Leydig cell tumors or stromal luteomas.

Although the average age at presentation of patients harboring SCTNOS is 43 years (10 to 15 years earlier than stromal luteomas and/or Leydig cell tumors), these tumors have been diagnosed from early childhood to the ninth decade of life (154). In addition, these generally solid yellow tumors are larger than the other SCTs. The average size at diagnosis approximates 8.5 cm (range, 1.2 to 45.0 cm). Furthermore, a higher frequency of bilaterality (5%) in advanced disease is encountered with these neoplasms. In their review of 63 collated cases, Hayes and Scully (154) reported that 81% of cases had localized disease (stage I), 6% had stage II disease, and 13% had stage III or IV disease. Curiously, they noted the average age (54 years) of patients with advanced disease was 10 years older than the group as a whole. At least in part, these findings reflect the absence of documented advanced malignancies during the first 2 decades of life.

Clinical signs and/or symptoms of androgen excess ranging from heterosexual precocity in prepubertal girls to amenorrhea, hirsutism, and/or virilization during the reproductive and/or postmenopausal ages prompt the majority of patients to seek medical advice (154,155). Not infrequently, the duration of these androgenic changes may have extended over many years (156). Additional concerns at presentation include increasing abdominal girth reflecting tumor size and, rarely, ascites, abdominal pain, cushingoid symptoms, and irregular uterine bleeding. The latter may represent clinical manifestations of estrogen excess (154,157), which has been suggested to occur at a frequency of 6% to 23%. Whether the source of estrogen is *de novo* synthesis by the tumor or from peripheral conversion of androgens remains to be determined. Isosexual precocious pseudopuberty has been detected in young girls harboring SCTNOS (154,158,159). An additional 10% to 15% of patients are asymptomatic, with tumors being detected incidentally during routine pelvic examination or at the time of hysterectomy or other surgical interventions.

The steroid hormone-secreting capacities of SCTNOS are more diverse than those of most SCTs. Whereas approximately 1 in 4 patients does not demonstrate clinical manifestations

of hormonal imbalances, the majority of patients with SCTNOS have evidence of androgen excess (10%–15% estrogen excess), and a lesser percentage have evidence of cortisol excess. These excesses are demonstrable via assessment of end-organ responses and serum/plasma steroid levels. Whereas elevated plasma levels of corticosteroids are typically observed in conjunction with SCTNOS, the number of overt presentations with Cushing's syndrome is limited (158,160–162). However, 17% of the clinically malignant tumors reported by Hayes and Scully (154) were associated with Cushing's syndrome. The serum testosterone and androstenedione levels are invariably elevated, as are urinary 17-ketosteroids; presumably, the latter reflect the level of excess androstenedione production.

Pathology

Gross Features

The tumors are typically solid, well circumscribed, occasionally lobulated (Fig. 26.8), and average 8.4 cm in diameter (154). Approximately 5% are bilateral. They are typically yellow or orange but are occasionally red, dark brown, or black. Necrosis, hemorrhage, and cystic degeneration are occasionally observed.

Microscopic Features

On microscopic examination, the tumor cells are typically arranged diffusely but occasionally grow in nests, irregular clusters, thin cords, and columns. The polygonal to rounded tumor cells have distinct cell borders, central nuclei, and moderate to abundant amounts of cytoplasm that varies from eosinophilic and granular to vacuolated and spongy (Fig. 26.9). In approximately 60% of the cases, nuclear atypia is absent or minimal and mitotic activity is low (less than 2 mitotic figures [MFs] per 10 HPFs). In the remaining cases, grades 1 to 3 nuclear atypia (Fig. 26.3) is present, usually associated with an increase in mitotic activity (up to 15 MFs per 10 HPFs).

Prognosis

In contrast to the benign natural history of both ovarian Leydig cell tumors and stromal luteomas, SCTNOS are associated with a relatively high rate of clinical malignancy. In the largest series in the literature, 43% of patients with follow-up of

FIGURE 26.8. Steroid cell tumor; unclassified. The sectioned surface of the tumor is lobulated and was yellow-orange in the fresh state. This tumor was from a 9-year-old virilized girl.

FIGURE 26.9. Steroid cell tumor: The tumor cells are large and rounded and laden with lipid vacuoles.

Source: Reprinted with permission from Hayes MC, Scully RE. Ovarian steroid cell tumors not otherwise specified [lipid cell tumors]: a clinicopathologic analysis of 63 cases. *Am J Surg Pathol.* 1987;11:835–845.

3 or more years demonstrated extraovarian disease either at primary surgery or during subsequent follow-up (163). Unfortunately, to date, salvage therapy has been abysmal. Multiple factors appear to correlate with the frequency of disseminated disease including age, stage, tumor size, mitotic activity, tumor necrosis, hemorrhage, and symptoms of Cushing's syndrome. The average age of patients with clinical malignancies was 16 years older than patients without metastatic disease and having had 3 or more years of observation. No clinically malignant cases have been reported to date in patients less than 20 years of age. All malignant SCTNOS were reported to measure 7 cm or more in greatest diameter (154). In fact, 78% of all tumors 7 cm or larger were malignant, whereas only 21% of all benign tumors exceeded this dimension. The most cogent determinant correlating with malignant potential was mitotic activity, with 92% of malignant tumors displaying 2 or more MFs per 10 HPFs. Similarly, in the presence of necrosis, 86% were malignant; if hemorrhage was present, 77% were malignant. In addition, 3 of 4 patients (17% of all malignant cases) with recognizable Cushing's syndrome harbored clinically malignant disease (154).

Although the majority of recurrences become clinically manifest within 3 years of diagnosis, Hayes and Scully (154) reported that 22% of recurrences occurred after 3 years and that, in fact, all of these cases occurred after 5 years; the longest interval witnessed was 19 years. Therefore, the duration of post-treatment surveillance should be adjusted accordingly. The only currently available utilizable markers for SCTNOS include the steroid hormones that were elevated prior to definitive treatment.

TREATMENT

The definitive management of SCSTs is dependent on 1 or more of the following: surgical stage, histologic subtype, patient's age and desire for fertility preservation, and various prognostic factors. Surgical resection alone is sufficient for SCSTs lacking malignant potential. Postoperative adjunctive therapy should be considered for patients with advanced disease and Sertoli-Leydig cell tumors with poor differentiation or heterologous elements (164).

Operative Management

Surgery remains the cornerstone of treatment for patients with SCSTs. Definitive therapy for SCSTs commences with an abdominal exploration through an adequate vertical midline incision. Following sampling of peritoneal washings for cytologic assessment, inspection and palpation of the viscera are conducted to detect macroscopic disease. Fertility-sparing surgery with unilateral salpingo-oophorectomy appears appropriate for patients with stage IA disease wishing preservation of their reproductive potential. In a review of the 1988 to 2001 SEER database, Zhang et al. identified 376 patients with ovarian SCST (165). The survival for the group of 110 patients with stage I-II disease who underwent conservative surgery without hysterectomy was similar to that of patients who underwent standard surgery. For older patients or those with advanced-stage disease or bilateral ovarian involvement, abdominal hysterectomy and bilateral salpingo-oophorectomy are usually indicated. Resection of the ovarian tumor constitutes sufficient therapy for the essentially benign neoplasms, including thecomas, fibromas, gynandroblastomas, stromal luteomas, Leydig cell, sclerosing stromal, Sertoli cell, and well-differentiated SLCTs. Furthermore, sex cord tumors with annular tubules associated with PJS are also considered to be benign and can be similarly managed, but it is imperative that the endocervix be evaluated and subsequently monitored for the potential development of an AMC. Conversely, histologic confirmation of GCTs, intermediate or poorly differentiated Sertoli-Leydig cell tumors, SCSTs with annular tubules independent of PJS, and steroid cell tumors not otherwise specified will require definitive surgical staging. This includes multiple peritoneal biopsies, omentectomy, and resection of grossly suspicious pelvic or paraaortic lymph nodes. Careful inspection of the peritoneum is critical as residual disease is strongly correlated with recurrence. However, there appears to be little benefit to performing routine lymphadenectomy in the absence of grossly suspicious lymph nodes. In 3 series totaling 180 patients with GCTs and SLCTs, no lymph node metastases were found among those who underwent pelvic and/or paraaortic lymphadenectomy (166–168). Furthermore, isolated retroperitoneal recurrences are rare. In 34 patients with recurrent GCTs, 2 recurred in the retroperitoneum only; 2 in the pelvis and retroperitoneum; and 1 in the pelvis, abdomen, and retroperitoneum (166). In another series of 87 patients, only 2 of 18 recurrences were isolated to the retroperitoneum (167). Overall, only approximately 10% to 15% of first recurrences involve the retroperitoneum. Following careful surgical staging, in the absence of extraovarian disease conservation of the uterus and contralateral ovary is reasonable in patients wishing preservation of fertility. However, if the uterus is preserved a thorough curettage must be performed in all patients with estrogen-producing tumors whether they are considered to be benign or potentially malignant (4). If maintenance of fertility is not a concern or if extraovarian spread of disease is documented, a hysterectomy and residual salpingo-oophorectomy should be performed. Although no randomized evidence exists pertaining to the efficacy of cytoreduction in SCSTs, based on the benefits observed with their epithelial counterparts, we endorse an aggressive maximum effort at primary surgery if metastatic disease is encountered. In a recent multivariate analysis of 176 patients with GCTs, only residual disease after primary surgery and tumor size were predictive of recurrence (37). The value of secondary tumor reduction continues to be controversial but appears to be meritorious for the more indolent tumor types such as GCTs and SCTATs not associated with PJS. Repeat cytoreduction frequently affords these patients extended palliation. It is therefore mandatory that the surgeon have the technical expertise to facilitate optimal surgical management.

Postoperative Management and Management of Recurrent Disease

Granulosa Cell Tumors (Adult)

The vast majority of women with stage I disease have an excellent prognosis after surgery alone and do not require adjuvant therapy. For those with stage IC disease, consideration can be given to adjuvant therapy on an individualized basis. Most women presenting with stages II–IV disease would be advised to have postoperative therapy depending on their individual characteristics.

Whereas some investigators have reported improved outcomes in patients treated with adjuvant radiation therapy, other investigators have found no clear value to the use of adjuvant radiation therapy (4,6,16,169). Because of the rarity of GCT, it is difficult to conduct prospective trials in these patients. Two retrospective reports provide some data on the use of radiotherapy. Savage et al. reviewed the courses of 62 women treated for adult GCTs at the Royal Marsden Hospital from 1969 to 1995 (170). Thirty-eight (61%) had stage I disease. Eleven of the stage I patients had adjuvant pelvic radiation. The 10-year disease-free survival of these patients was 77% versus 78% for stage I patients treated with surgery alone. Unfortunately, neither complete surgical staging information nor the features that led to the selection of patients for adjuvant radiation was provided. For 8 patients with inoperable disease (or residual disease postoperatively), radiation resulted in complete responses in 4 (50%) that lasted 16 months to 5 years.

Wolf et al. reported on 34 patients with GCTs treated with radiation at the M.D. Anderson Cancer Center, 14 of whom had measurable disease (169). Six of the 14 (43%) had a clinical complete response. Three of the responders were alive without evidence of disease 10 to 21 years after radiation.

The Gynecologic Oncology Group (GOG) has reported the largest series of women with ovarian SCSTs treated with chemotherapy. They used 4 cycles of cisplatin, bleomycin, and etoposide (BEP) (171). Eligible patients had incompletely resected stage II to IV or recurrent disease. Seventy-five patients entered but 18 were ineligible because of incorrect histology or disease status. Of the 57 eligible patients, 41 had recurrent disease and 16 had primary disease. Thirty-nine had gross residual disease following surgery. Forty-eight had GCTs, 7 had SLCTs, one had a malignant thecoma, and 1 had an unclassified SCST. This chemotherapy combination was considered to be active, with 11 of 16 primary-disease patients and 21 of 41 recurrent-disease patients remaining progression free at a median follow-up of 3 years. Recognizing the prolonged natural history of these tumors, longer follow-up of this cohort will be important. The regimen was fairly toxic, with 2 bleomycin-related fatalities among the first 6 patients treated with the initial bleomycin dose of 20 U/m² (maximum 30 U) weekly for 9 weeks. The bleomycin dose was then reduced (20 U/m² every 3 weeks × 4 cycles) with no mention of further toxicity. Grade 4 myelotoxicity occurred in 61% of the patients. The value of bleomycin in the treatment of this tumor type remains in question (172).

Gershenson et al. (173) also reported on the use of BEP in a group of 9 women with poor-prognosis SCSTs of the ovary (7 had metastatic disease). The median progression-free survival was 14 months, with a median survival time of 28 months. These investigators, in the same publication, describe activity with paclitaxel in patients with granulosa cell tumors who have failed platinum-based therapies. In an earlier series, Gershenson et al. (163) found that cisplatin, doxorubicin, and cyclophosphamide were shown to have activity in the treatment of metastatic ovarian stromal tumors, including two

Sertoli-Leydig cell tumors. The overall response rate was 63% in this series.

The management of patients with recurrent disease must be individualized. Given the characteristic indolent growth pattern of GCTs, with long disease-free intervals, surgical resection of disease recurrence is often the initial step in the management of appropriate patients. Pecorelli et al. treated 38 patients with advanced (n = 7) or recurrent (n = 31) GCTs with cisplatin, vinblastine, and bleomycin (PVB) on a prospective trial through the European Organization for Research and Treatment of Cancer (EORTC) (174). Of the 7 women who presented with advanced disease (stages II–IV), 1 was alive and disease-free at 81 months. Five died between 4 and 12 months after the start of PVB, and another was alive with disease at 2 months. Among the 31 women with recurrent disease, 7 were alive without further evidence of disease from 24 to 81 months from the start of PVB. Consistent with the indolent course observed with GCTs in some women, another 11 women were alive with disease at a mean of 45 months from the start of PVB (median, 39 months).

The wisdom of using a germ cell-like regimen for stromal tumors is questionable. Uygun et al. reported on a small series of 11 women with recurrent GCTs (175). Most had cyclophosphamide, Adriamycin (doxorubicin), and cisplatin (CAP) in the adjuvant setting. Four were treated with cyclophosphamide and cisplatin for recurrence and survived 35 to 73 months after recurrence.

Taxanes have also been reported to have activity in SCSTs. A case report documented a dramatic response to paclitaxel in a patient with a GCT 2 years following cessation of platinum-based therapy (176). Subsequently, Brown et al. reported a retrospective review of the M.D. Anderson Cancer Center experience with taxane therapy in 44 patients with newly diagnosed or recurrent SCSTs (177). Eleven patients received paclitaxel and a platinum drug for newly diagnosed SCST; all were alive at the time of the study, with a median follow-up of 52 months. Of 37 patients treated with a taxane for recurrent SCST, 7 had no measurable disease after secondary cytoreductive surgery, and 30 had measurable disease. The response rate in the latter cohort was 42%. In a follow-up study, Brown et al. retrospectively compared the efficacy and side effects of taxanes, with or without platinum, to the combination of BEP (178). The outcomes of the 2 groups were similar, but the side effects associated with the BEP regimen appeared to be greater. The authors concluded that taxane and platinum chemotherapy warrants further investigation in SCSTs. The GOG is currently conducting a phase 2 trial of paclitaxel in women with stromal tumors with measurable disease (GOG protocol 187)—either previously untreated or recurrent. In addition, a GOG randomized phase 2 study of paclitaxel and carboplatin versus BEP in patients with SCSTs is also ongoing.

Considerable rationale exists for the utilization of hormone-based approaches in GCTs. A proportion of these tumors express steroid hormone receptors (179). Responses of GCTs, occasionally long-term, to medroxyprogesterone acetate and to GnRH antagonists have been reported (180–184). Fishman et al. (185) treated 6 patients with recurrent or persistent GCTs with monthly intramuscular injections of leuprolide acetate. Four patients had received prior cisplatin-based chemotherapy. Five patients had evaluable disease: 2 had partial responses and 3 had stable disease. The leuprolide was well tolerated.

Aromatase inhibitors have also been used in GCTs. Three reports have documented remissions in 7 women who received aromatase inhibitors for recurrent GCTs (186–188).

Anti-angiogenesis drugs have also been reported to have activity in sex cord-stromal tumors. Farkkila et al. found that VEGF and VEGF-2 were highly expressed in primary and recurrent GCTs (189). In addition, although tumor VEGF

protein expression was not predictive of tumor recurrence in this series, high levels of circulating VEGF were found in the serum of women with primary GCTs. Tao et al. reported on 8 patients with recurrent GCTs (7 adult and 1 juvenile) who were treated with bevacizumab (190). One patient had a complete response and 2 had a partial response. The GOG has recently completed a phase II study of bevacizumab for recurrent sex cord-stromal tumors, the results of which are pending.

Granulosa Cell Tumors (Juvenile)

Calaminus et al. (191) reported the outcome of 33 patients with JGCTs—24 treated with surgery alone and 9 with surgery and cisplatin-based chemotherapy. There have been 6 relapses, with 60 months median follow-up: 2 of 20 stage IA, 2 of 8 stage IC, and 2 of 5 stage IIC to IIIC. Three patients with stage IIC to IIIC disease treated with adjuvant cisplatin-based therapy remain disease-free at 46 to 66 months after diagnosis. Furthermore, Powell and Otis (192) reported short-term disease control in 2 teenagers with stage III JGCTs following surgery and cisplatin-based chemotherapy.

German investigators published their 15-year experience (1985–2000) with 54 SCSTs in children and adolescents (74). Forty-five were JGCTs. Twelve received adjuvant chemotherapy for stages IC to IIIC disease. BEP and cisplatin, etoposide, and ifosfamide (PEI) were the most commonly used regimens. Six patients remained in remission after adjuvant chemotherapy from 15 to 106 months later. A seventh developed a contralateral JGCT 10 years after her initial primary tumor. Five of the 12 have recurred, 3 of whom died 16 to 28 months from diagnosis.

Powell et al. have reported a patient with long-term disease-free survival following salvage chemotherapy for recurrent JGCT (193). The patient had presented with stage IIIC disease initially treated by resection of all gross disease followed by carboplatin and etoposide for 6 cycles. She recurred 13 months later with limited disease in the liver and a mass at the inferior aspect of the spleen. She underwent gross total resection followed by 6 cycles of bleomycin and paclitaxel. She was disease-free 44 months later, delivering a normal baby at cesarean section.

Sertoli-Leydig Cell Tumors

Therapy for those few individuals presenting with high-stage SLCTs, as well as for individuals with recurrent disease, must be individualized. The effectiveness of radiation therapy is unknown (113). Reports exist of responses to vincristine, actinomycin D, and cyclophosphamide (VAC) and cisplatin, doxorubicin, and cyclophosphamide (163,194). Schneider et al. reported 3 patients with SLCTs who were treated with platinum-based chemotherapy (74). One patient with stage IC disease with intermediate differentiation received 2 cycles of the combination of cisplatin and etoposide and was disease-free at 47 months. Two other patients, both of whom had stage IC poorly differentiated SLCTs, were dead of tumor at 7 and 19 months after receiving either BEP or PEI. Given the functional hormonal nature of many of these neoplasms, consideration could also be given to some form of hormonal manipulation, such as luteinizing hormone-releasing agonists or antagonists (195).

Recently, the Italian cooperative group, Multicentre Italian Trials in Ovarian Cancer (MITO), reported their experience with 21 patients with SLCTs (196). Five patients received adjuvant chemotherapy—platinum-based chemotherapy in 4 (BEP in 2 and paclitaxel/carboplatin in two), and 1 received

the combination of methotrexate, 5-fluorouracil, and cyclophosphamide. Three of the 5 patients subsequently died of disease. Seven patients (1 stage IAG1, 3 stage IAG2, 1 stage ICG2, and 2 stage IIICG3) relapsed, 4 of whom had stage IA disease and did not receive adjuvant chemotherapy. Five of these patients were treated with surgery plus chemotherapy, 1 received chemotherapy alone, and 1 received palliation only. All 6 patients who received chemotherapy were treated with platinum-based regimens—either BEP or paclitaxel/carboplatin. At the time of the report, 2 patients—one with stage IAG1 and one with Stage IAG2—were clinically disease-free, and the other 5 were dead of disease.

Sex Cord Tumor with Annular Tubules

Given the rarity of this tumor, the collective experience with systemic therapy for SCTATs is scant. Their endocrine activities suggest that the tumors may retain responsiveness to perturbation of gonadotropin levels. A recent case report documents a complete response to etoposide, bleomycin, and cisplatin in a patient with recurrent SCTAT (143).

MOLECULAR PATHOGENESIS

Our current knowledge regarding various autocrine and endocrine regulatory mechanisms influencing ovarian function, the overexpression of inhibin in several SCSTs, the alterations in ovarian steroidogenesis, and the changes in circulating gonadotropin levels in SCSTs provide clues regarding the pathogenesis of these tumors. Investigations to date exploring the interactive regulatory mechanisms of inhibin, activin, follistatin, and follicle-stimulating hormone (FSH) have predominantly utilized GCTs. Follicle-stimulating hormone provides a fundamental regulatory role in the differentiation processes of granulosa cells during the early stages of follicle development. Specifically, FSH stimulates cell proliferation (mitosis), increases the availability of cell-surface prolactin and luteinizing hormone receptors, and induces aromatase activity, resulting in increased estradiol production. Other growth-regulatory factors such as insulin-like growth factor and epidermal growth factor modulate these actions, including the enhancement of the mitogenic effects of FSH. In addition, FSH secretion from the anterior pituitary is modulated in part by the serum levels of inhibin, activin, estrogens, and/or androgens.

Inhibin, a heterodimeric glycoprotein hormone composed of an α -subunit and 1 of 2 β -subunits, is secreted by the granulosa cells of the ovary (197). Inhibin A consists of α A and β A; inhibin B consists of α B and β B. Petraglia et al. (198) demonstrated that serum inhibin B was dramatically increased in 8 of 9 patients with GCTs, while inhibin A was slightly increased in all patients. Its major physiologic function is to inhibit the secretion of FSH by the anterior pituitary gland (199). Inhibin is expressed in excessive quantities by GCTs. Although it maintains its regulatory function pertaining to FSH suppression, it appears to be ineffective in controlling estrogen production and cell proliferation within the gonad. Robertson et al. have recently reviewed the various serum-based assays for inhibin (200).

Activin, also a peptide hormone of ovarian granulosa cell origin, is composed of 2 β -subunits that are identical to those of inhibin. In contrast to inhibin, activin stimulates the secretion of FSH, induces the production of estradiol while having a negative impact on progesterone production, and promotes granulosa cell differentiation (199).

Several investigative teams are pursuing studies to elucidate the underlying genetic and biologic changes that give rise to SCSTs, especially GCTs. Lin et al. performed comparative genomic hybridization of a set of 37 adult-type GCTs (36 primaries, 1 recurrence) obtained from 5 hospitals in Taiwan (201). All patients had stage I disease except for 1 stage III patient with limited disease at initial diagnosis. Twenty-two (61%) of the 36 primary tumors had chromosomal imbalances. The non-random changes included loss of 22q in 31% of tumors, gain of chromosome 14 in 25% of tumors, and gain of chromosome 12 in 14% of tumors. Monosomy 22 frequently coexisted with trisomy 14. High-level amplification, as can be seen in many aggressive carcinomas, was not detected in any of these GCTs. Findings were similar to those reported by Mayr et al. (202). As a sole abnormality, trisomy 12 has also been found in fibromas and fibroepitheliomas, in addition to GCTs (203,204). Menczer et al. looked for HER2/neu expression in 12 GCTs and saw no immunohistochemical staining (205). An Austrian group looked at the immunohistochemical expression of the HER family of receptors—HER1 (EGFR), HER2, HER3, and HER4—in 38 adult GCTs and 2 of the juvenile type (206). Thirty-one cases (77.5%) were positive for at least 1 of the receptors (EGFR, HER3, or HER4). None of the 40 cases showed a positive reaction for HER2. Twenty-six of 40 (65%) showed reactivity for EGFR. HER3 and HER4 expression were observed in 18 (45%) and 23 (57.5%) tumors, respectively. Kusamura et al. also looked for HER2 expression in 18 GCTs: all cases were negative (207). They also showed a markedly low likelihood of immunohistochemical staining for p53 and low proliferative indices in these tumors.

Richards et al. used a mouse model to investigate granulosa cell tumorigenesis (208). They showed that formation of GCTs by stable activation of β -catenin (CTNNB1) in granulosa cells is accelerated by concomitant *Kras* activation or *PTEN* loss. It has yet to be confirmed if these are crucial pathways in the development of GCTs in humans. Recently, Shah and colleagues performed whole-transcriptome paired-end RNA sequencing on 4 GCTs (209). They discovered a point mutation missense point mutation, 402C→G (C134W), in *FOXL2*, a member of the forkhead-winged helix family of transcription factors. This gene is known to be involved in ovarian differentiation and is required for the normal development of granulosa cells (210,211). They confirmed the presence of this mutation in 86 of 89 adult GCTs, while it was present in only 1 of 10 juvenile GCTs. Interestingly, review of the 3 mutation negative adult GCTs revealed that 2 were in fact not true GCTs. The use of immunostaining for *FOXL2* rather than molecular screening was subsequently shown to be diagnostically useful with sensitivity and specificity of 80% and 99% for SCSTs (212). These results support a molecular basis for the disparate clinical course observed between juvenile and adult GCTs, provide a means to improve diagnosis in difficult cases, and suggest that *FOXL2* is a key driver of GCT pathogenesis.

The other major recent finding has been that of *DICER1* mutations in ovarian SCSTs (213–215). Schultz et al. reported that, among 296 kindreds including 325 children with pleuropulmonary blastoma (PPB), 3 children had both PPB and SLCT (213). Among family members of PPB patients, they identified 6 ovarian SCSTs. Germline *DICER1* mutations were identified in 4 of 6 patients with SCSTs from PPB kindreds and in 2 of 3 children with ovarian SCSTs and no personal or family history of PPB. In another report, Heravi-Moussavi et al. found somatic *DICER1* mutations in the RNase IIIb domain in 26/43 (60%) SLCTs, including 4 tumors with additional germline *DICER1* mutations (214). Thus far, the finding of neither of these mutations has translated into a therapeutic target.

Chu et al. examined the estrogen receptor isoform gene expression in a small series of GCTs and serous cystadenocarcinomas

of the ovary (4 of each) (216). They saw widespread expression of estrogen receptor (ER)- α in both tumor types but at relatively low levels, similar to or less than what is seen in the endometrium. ER- β expression in the GCTs, however, was several-fold higher than that of ER- α . Fuller and Chu have provided an informative review of various signaling pathways that are important in the regulation of growth, differentiation, and apoptosis of normal granulosa cells, which may contribute to the molecular pathogenesis of GCTs (217). Because of the important role of the insulin-like growth factor (IGF) system in development of the dominant follicle, and its contribution to epithelial ovarian cancer, Alexiadis et al. characterized the expression of several components of the IGF system in a series of nine GCTs (218). Interestingly, pregnancy-associated plasma protein-A expression was highest in the GCTs. PAPP-A is a metalloproteinase synthesized by granulosa cells, the activity of which leads to increased IGF bioavailability. Anttonen et al. studied samples from a cohort of 80 GCT patients from the University of Helsinki and examined several growth regulatory factors known to be important in normal granulosa cell function, including anti-müllerian hormone, inhibin- α , and GATA transcription factors (219). They found a correlation between high GATA-4 expression and higher likelihood of recurrence.

The natural history of SCSTs is uniquely different from that of their epithelial counterparts and provides an intriguing tumor model. The vast majority of these neoplasms are characteristically of low malignant potential. They are typically unilateral and remain localized, retain hormone-secreting functions, and infrequently develop recurrences, many of which are delayed. In contrast, a small percentage of otherwise phenotypically similar tumors demonstrate a more virulent course and are generally refractory to therapy. The SCST subtypes display a bimodal age distribution, notably with JGCTs, SSCTs, SLCTs, and SCTATs occurring predominantly during the first 3 decades of life. Furthermore, the association of these tumors with several uncommon congenital disease entities, such as enchondromatosis, leprechaunism, and PJS, occurs at frequencies that exceed mere chance. Uniquely, several of these functioning neoplasms, including AGCTs, JGCTs, SLCTs, and SCTATs, overexpress growth-regulatory substances including inhibin, müllerian-inhibiting substance, and follicle-regulating protein. Given the limited number of ovarian SCSTs available for study, our current understanding of the mechanism of oncogenesis in these tumors is understandably limited.

SUMMARY

The principal problem related to the study of SCSTs and the development of effective therapy is their rarity. Although this interesting group of tumors has been studied extensively from a histologic standpoint, there are surprisingly few features that distinguish tumors that are more likely to recur or have aggressive behavior, and much of the information is conflicting.

Surgery remains the cornerstone of treatment for patients with SCSTs. Furthermore, for young patients desirous of fertility preservation, fertility-sparing surgery is possible in a large proportion related to the propensity of these tumors to be unilateral and nonmetastatic. Patients who appear to have a worse prognosis and for whom postoperative therapy would appear to be indicated include those with metastatic SCSTs of any histotype and those with stage I poorly differentiated SLCTs. For patients with SCSTs confined to the ovary, postoperative therapy is not recommended. For those with stage IC disease, the issue of postoperative therapy is unresolved.

Standard postoperative treatment consists of platinum-based chemotherapy. The BEP regimen is currently the most popular combination. However, this is a relatively toxic regimen; hence,

the interest in alternative combinations, such as taxane/platinum chemotherapy. However, more study of this latter combination is warranted. An ongoing GOG study should help resolve this issue.

Beyond platinum-based chemotherapy, there is no consensus concerning recommended second-line or salvage therapy.

Hormonal medications clearly have some degree of activity in GCTs. Anti-angiogenesis agents hold promise. In addition, there is probably a limited role for radiation. This gap in our armamentarium underscores the need for novel target-based therapeutics developed through the study of the genes and pathways involved in the pathogenesis of these neoplasms.

Gestational Trophoblastic Disease: Molar Pregnancy and Gestational Trophoblastic Neoplasia

JULIAN C. SCHINK ■ JOHN R. LURAIN

Gestational trophoblastic disease (GTD) describes a continuum of interrelated lesions that arise from abnormal proliferation of placental trophoblasts, ranging from benign hydatidiform mole to invasive mole, malignant choriocarcinoma (CCA), and placental site trophoblastic tumor (PSTT) (Table 27.1). Hydatidiform moles, both complete and partial, are benign lesions that resolve following uterine evacuation in the vast majority of cases. Persistent GTD refers to disease that does not resolve after molar evacuation or that becomes malignant and requires active management. Invasive moles, CCA, and PSTT, as well as a variant of PSTT called epithelioid trophoblastic tumor (ETT), are collectively referred to as gestational trophoblastic neoplasia (GTN), with varying degrees of malignant potential. GTN most commonly arises after a molar pregnancy, though it can develop after any pregnancy. Historically, GTD was associated with high rates of morbidity and mortality. Hydatidiform mole was associated with serious complications, and the mortality rate for invasive mole approached 15%. The mortality rate for CCA was near 100% if metastatic disease was present and 60% for nonmetastatic disease even if hysterectomy was performed. Earlier detection with ultrasonography, the use of human chorionic gonadotropin (hCG) as a disease-specific biomarker, advances in uterine evacuation, and the introduction of chemotherapy into the management of GTN (1) have significantly decreased the risk of death associated with GTD and have allowed many women to preserve their fertility after treatment. This chapter will describe the epidemiology and pathology of molar pregnancy and GTN and will discuss the changes in diagnosis and management that have transformed GTN from one of the most deadly to one of the most curable solid tumors in women, with cure rates higher than 90%, even in the presence of metastasis (2,3).

EPIDEMIOLOGY

Epidemiologic data for GTD are unreliable, primarily due to inconsistent case definitions, no centralized databases, and the rarity of certain forms of the disease. Similarly, defining the risk factors that contribute to the development of GTD has been challenging, with an inability to adequately identify at-risk populations and a lack of control groups (4). Based on available data, hydatidiform mole develops in women during their reproductive years (5), with an incidence that varies widely across different geographical regions. In North America, Australia, New Zealand, and Europe, the incidence of molar pregnancy has been reported as 0.6 to 1.1 per 1,000 pregnancies, but it is 2- to 3-fold higher in Southeast Asia and Japan (2.0 per 1,000 pregnancies) (6–8). In Taiwan, hydatidiform mole occurs in 1 in

125 pregnancies, whereas the incidence in the United States is approximately 1 in 1,500 pregnancies. In a study from Ireland, the incidence of complete and partial mole was reported as 1 in 1,945 and 1 in 695 pregnancies, respectively (9).

Despite this geographical variation, the risk of hydatidiform mole has not been linked to any specific ethnic or racial differences, cultural factors, or differences in reporting of hospital-based and population-based data (10–12). However, several studies have reported a link between molar pregnancy and socioeconomic and dietary factors, specifically, that the risk of complete molar pregnancy increases with decreased consumption of vitamin A (carotene) and animal fat (13,14). Regions with a higher incidence of vitamin A deficiency also have a higher incidence of molar pregnancy. A history of infertility is also associated with increased risk of complete and partial mole (15), and a history of spontaneous abortion increases the risk of both complete and partial moles 2- to 3-fold compared with women without a history of miscarriage (15–17).

The two strongest risk factors for complete hydatidiform mole are maternal age and prior molar pregnancy (17). Both very young women and women over the age of 40 have a higher risk of complete molar pregnancy, with older women having a 5- to 10-fold higher risk (18,19). In women over the age of 50, 1 in every 3 pregnancies is molar (4). These observations suggest that the ova of older women are predisposed to the abnormal fertilization events that lead to hydatidiform mole. The risk of a second complete molar pregnancy is 1%, approximately 10- to 20-fold higher than the risk of molar pregnancy in the general population (20,21), and the risk of a third mole is 15% to 20% (22,23), regardless of a change in partner (24).

Familial repetitive hydatidiform mole (17) has been linked to a missense mutation in the *NLRP7* locus (25,26) on chromosome 19 (27); in one report, this mutation was present in 60% of patients who had two molar pregnancies (28). The mutated gene is involved in maternal imprinting (29) and is seen in familial clusters of complete moles of biparental origin rather than androgenetic origin (26,30).

There is less information regarding the epidemiology of partial molar pregnancy, though it is clear that it differs from that of complete molar pregnancy (18,19). Partial mole does not appear to be linked to vitamin A deficiency (31) or advanced maternal age (17), but is associated with a history of irregular menstruation and use of high estrogen-containing oral contraceptives (31).

Locally invasive GTN develops in approximately 15% of patients after molar evacuation. CCA occurs in 1 in 50,000 pregnancies (including term, miscarriage, abortion, or ectopic) (32). CCA is 1,000 times more likely to develop after a complete molar pregnancy than after other pregnancy events, with half of all CCA cases arising from molar pregnancies. The risk of

CCA increases in women with advanced maternal age and prior hydatidiform mole, and is higher in women of Asian, American Indian, and African American descent (12). Menarche after age 12, light menstrual flow, and long-term use of oral contraceptives are also associated with a higher risk of CCA (33), though the association between postmolar GTN and oral contraceptive use is not entirely clear (34,35). Women with type A blood also have an increased risk of CCA (7,36).

PSTT and ETT are extremely rare forms of malignant GTD, and there are insufficient data to characterize the epidemiology or risk factors. Approximately 95% of PSTT and ETT lesions develop after a term pregnancy or nonmolar abortion (37), often several months or even years later.

PATHOLOGY AND CHROMOSOMAL FEATURES**Trophoblastic Differentiation and GTD**

Molar pregnancies and GTN originate from the placental trophoblast, which is derived from the outermost layer of the blastocyst, called the trophoctoderm (38). The trophoblast is composed of cytotrophoblast, syncytiotrophoblast, and intermediate trophoblast. Syncytiotrophoblast invades the endometrial stroma upon implantation of the blastocyst and secretes hCG and other proteins to regulate the implantation site microenvironment. Cytotrophoblast fuses with syncytiotrophoblast to form the chorionic villi that cover the chorionic sac. Nonvillous cytotrophoblast differentiates into intermediate trophoblast, categorized as either implantation site or chorion type. Implantation site intermediate trophoblast loses the ability to proliferate but invades the maternal decidua and myometrium in a highly controlled manner, migrating to the maternal spiral arteries to facilitate oxygen and waste transfer between the fetus and the mother (Fig. 27.1).

Invasion of healthy trophoblast into the maternal endometrium is a normal, tightly regulated event in pregnancy that is required for the vascular connection between the fetus and the mother. When regulatory mechanisms are impaired, invasive and vascular tumors arise. For example, recent work has described an inhibitory effect of TGF- β and a proteoglycan, decorin, on nonvillous trophoblast cell growth, migration, and invasion, and this negative regulation is lost in trophoblast lesions (39,40).

Most GTD lesions (except partial mole) derive from the fetus and not from the mother, and therefore contain only paternal

genetic material (38). A large body of work on the immunobiology of GTD has suggested that a maternal immunologic response is activated by paternal antigens in the trophoblastic cells of GTD lesions, thereby promoting their regression and sensitizing them to chemotherapy; conversely, women with persistent GTD or aggressive disease may have greater histocompatibility such that the paternal antigens do not elicit a strong immune response from the mother (41).

All three types of trophoblast can proliferate to produce GTD lesions (42), and each type expresses different antigens that have been useful in the immunohistochemical analysis and differential diagnosis of trophoblastic lesions (43); they may also provide insight into the pathogenic mechanisms underlying GTN (Table 27.2). Expression of Ki67, proliferating cell nuclear antigen, and p53 are significantly higher in GTD compared with normal tissues and can differentiate between GTD and spontaneous abortion (44). p63 isoforms are differentially expressed in cytotrophoblast and intermediate trophoblast (45) and may be useful in differentiating between PSTT (p63 negative) and ETT (p63 positive). HLA-G is also expressed in intermediate trophoblasts but not in villous cytotrophoblasts or syncytiotrophoblasts, and may be useful in the diagnosis of various GTD lesions (46). Several growth factors and oncogenes are abnormally expressed in molar tissues and CCA (15,47,48). Both complete mole and CCA overexpress c-myc, c-erb2, and bcl-2. Epidermal growth factor receptor (EGFR) was found to be more highly expressed in CCA and complete moles compared with normal placenta and partial moles, suggesting that EGF family members may be involved in GTN pathogenesis (49). In addition, there is increased expression of matrix metalloproteinase (MMP-1 and MMP-2) and decreased expression of tissue inhibitor of metalloproteinase (TIMP)-1 in CCA compared with either hydatidiform

mole or normal placenta, implicating the dysregulation of extracellular matrix (ECM) in the invasion and metastasis of CCA (50). Characterizing the molecular pathogenesis of GTD is an active area of research that may reveal new diagnostic and prognostic markers, as well as lead to targeted therapies.

Hydatidiform Mole

Molar pregnancies arise from the proliferation of villous cytotrophoblast and syncytiotrophoblast, which produces lesions on the maternal decidua (51,52). A comparison of the characteristics and cytogenetics of complete and partial moles is provided in Table 27.3. Complete hydatidiform moles show early uniform enlargement of villi with hyperplastic and atypical trophoblast and do not contain a fetus/embryo or villous capillaries (Fig. 27.2). Most complete moles (approximately 90%) are 46,XX and arise from the fertilization of an “empty” anucleated egg—missing the pronucleus and maternal chromosomes—by a single sperm followed by duplication of paternal haploid chromosomes (Fig. 27.3) (53,54). The other 10% of complete moles are either 46,XY or 46,XX and are produced by dispermic fertilization of an anucleated egg. Some complete moles can also arise from the loss of maternal chromosomes during the first cleavage. Regardless of monospermic or dispermic fertilization, complete moles contain only paternal chromosomes (androgenetic), though maternal DNA is present in the mitochondria of the egg (55). The presence of excess paternal material leads to trophoblastic hyperplasia, with no formation of a fetus due to the absence of maternal chromosomal DNA. Loss of maternally imprinted genes and extra paternally imprinted genes may also inhibit embryo formation (56).

FIGURE 27.2. Complete hydatidiform mole. Upper left: large round chorionic villi with cistern formation; Upper right: large irregular contour with extensive trophoblastic proliferation; Lower left: gross morphology of large cystic chorionic villi; Lower right: chorionic villous stromal cells stain negative for p57.

FIGURE 27.3. Karyotypes of complete and partial hydatidiform mole. (A) Complete moles arise from the fertilization of an empty egg with a single sperm that then undergoes duplication (46,XX) or the fertilization of an empty egg with two sperm (46,XX or 46,XY). Complete moles therefore contain only paternal genetic material. (B) Partial moles are triploid (69,XXY; 69,XXX; or 69,YYY) and arise from either dispermic fertilization of a normal egg or duplication of chromosomes in a single sperm after fertilization of a normal egg.

In contrast, partial hydatidiform moles contain fetal/embryonic tissue, and the chorionic villi show varying degrees of focal enlargement and edema, predominantly syncytiotrophoblast hyperplasia, scalloping of the villous outline, prominent stromal inclusions, and functional villous circulation (Fig. 27.4) (57). Like incomplete moles, the trophoblast is hyperplastic but shows only mild atypia. In later stages of partial molar pregnancy, the fetus shows congenital abnormalities, such as syndactyly of the fingers and toes (57). The majority of partial moles are triploid, most often 69,XXY, with two sets of paternal chromosomes as a consequence of either dispermic fertilization of a normal egg or duplication of chromosomes in a single sperm after fertilization of a normal egg (Fig. 27.3) (51,56,58).

Invasive Mole

Invasive mole is a condition in which hydatidiform mole, with hydropic villi and proliferating trophoblast, has invaded the myometrium through the tissue or veins (Fig. 27.5). Molar villi may be observed on the uterine serosa, and extrauterine tubal and ovarian moles can occur (59). Invasive moles are less hydropic, and trophoblastic proliferation is easily seen (Table 27.3) (57).

Choriocarcinoma

Approximately 2% of women with complete moles may develop CCA, characterized by a mixture of cytotrophoblast and syncytiotrophoblast hyperplasia, hemorrhage, and necrosis, and the absence of chorionic villi (Fig. 27.6) (57). Direct invasion of the myometrium and vasculature is also present, which permits metastasis to the lungs, brain, liver, pelvis and vagina, kidney, intestines, and spleen. Immunohistochemical markers can confirm a histologic diagnosis of CCA, with tumors staining strongly for hCG and inhibin α in the trophoblast, human placental lactogen (hPL) and inhibin α in intermediate trophoblast, and cytokeratin in all trophoblast cells (Tables 27.2 and 27.3) (60). Ki-67 is diffusely expressed in approximately half of the cells (61).

Placental Site Trophoblastic Tumor

PSTT lesions are usually diploid and monomorphic, developing from placental implantation site intermediate trophoblast after a normal or aborted uterine pregnancy (62). PSTT lesions contain primarily mononuclear intermediate trophoblast without chorionic villi that infiltrates the uterine wall in sheets or cords between myometrial fibers (Fig. 27.7). Compared with CCA, there is less hemorrhage, necrosis, and vascular invasion, but there is a higher risk of lymphatic metastasis. hCG production is focal, leading to relatively lower serum levels (Table 27.3). These tumors may be diagnosed immunohistochemically, and contain diffuse cytokeratin and human placental lactogen (63), as well as inhibin α (60) and Mel-CAM (Table 27.2) (61). The Ki-67 labeling index is also usually elevated (>10%) in a neoplastic lesion of nonvillous trophoblast (61).

Epithelioid Trophoblastic Tumor

Epithelioid trophoblastic tumor (ETT) is a rare malignant tumor that arises from neoplastic transformation of chorion-type intermediate trophoblast (62). These lesions appear as nodules of mononuclear intermediate trophoblast, surrounded by hyalinized extracellular matrix within extensive necrotic tissue and with preserved blood vessel structure (Fig. 27.8 and Table 27.3). Intratumor hemorrhage and metastases are rarely observed.

Table 27.3 Clinicopathologic Features of Gestational Trophoblastic Diseases

Disease	Pathologic Features	Clinical Features
Complete mole	• Diploid (46,XX and some 46,XY) • No fetus or embryo • Diffuse swelling of villi • Diffuse trophoblastic hyperplasia	• Vaginal bleeding • Large for date uterine size • Bilateral theca lutein cysts • hCG can be >100,000 mIU/mL
Partial mole	• Triploid (69,XXY; 69,XYY; 69,XXX) • Abnormal fetus or embryo • Focal swelling of villi • Focal trophoblastic hyperplasia with mild atypia	• Symptoms of incomplete or missed abortion • Vaginal bleeding • hCG rarely elevated >100,000 mIU/mL
Invasive mole	• Trophoblastic hyperplasia • Swollen villi • Myometrial invasion	• Irregular postmolar vaginal bleeding • Persistent hCG elevation • <15% symptoms of lung/vaginal metastases
Choriocarcinoma	• Mixture of cytotrophoblast and syncytiotrophoblast hyperplasia • No villi • Myometrial invasion and metastatic potential • Hemorrhage • Necrosis	• Irregular postmolar vaginal bleeding • Persistent hCG elevation • Metastases and associated symptoms
PSTT	• Diploid • IT hyperplasia • No villi • Less hemorrhage and necrosis • High potential for lymphatic invasion and metastasis • Focal hCG production	• Low serum hCG • Enlarged uterus • hCG levels normal to 1,000 mIU/mL • Metastases and associated symptoms
ETT	• IT nodules surrounded by hyalinized ECM • Extensive necrotic tissue • Preserved blood vessel structure • Hemorrhage and metastases rare

Table 27.4 The Changing Clinical Signs of Molar Pregnancy

Clinical Sign	Incidence (%)	
	1970s	2010s
Vaginal bleeding	100	90
Uterine enlargement	54	28
Toxemia	22	1
Hyperemesis	28	8
Hyperthyroidism	10	<1
Trophoblastic emboli	2	<1
Bilaterally enlarged ovaries	15	15
Absence of fetal heart sounds	100	100

MANAGEMENT OF MOLAR PREGNANCY

Clinical Presentation

Approximately 80% to 90% of women with complete hydatidiform mole present with vaginal bleeding, occurring at 6 to 16 weeks gestation. Women may also present with larger uterine size than expected for gestational date, toxemia, hyperemesis, and hyperthyroidism in the first or second trimester. However, the widespread use of ultrasonography in developed countries and accurate hCG tests to evaluate vaginal bleeding have led to earlier diagnosis of molar pregnancy, and other clinical signs and symptoms are seen less often (Table 27.4) (67). hCG levels can be greater than 100,000 mIU/mL in a complete molar pregnancy, and there are no fetal heart tones (Table 27.3); however, hCG levels vary widely in individual patients, and with earlier ultrasound detection, patients may not present with extremely elevated hCG. It should also be emphasized that a high hCG level alone is not sufficient for a diagnosis of hydatidiform mole, and a confirmatory ultrasound should be performed. In approximately 15% of women with complete hydatidiform mole, ultrasound imaging reveals the presence of bilateral theca lutein cyst enlargement of the ovaries (5,67–69).

Partial hydatidiform mole presents quite differently from complete mole. The vast majority of patients—greater than 90%—present with symptoms of incomplete or missed abortion. Vaginal bleeding occurs in 75% of patients with a partial molar pregnancy, and uterine enlargement, hyperemesis,

ETT tumor cells show diffuse expression of immunohistologic markers, including cytokeratin and inhibin α (Table 27.2) (64). Cyclin E staining is higher in ETT than placental site nodule and can help in differentiating between the two (64–66).

FIGURE 27.7. Placental site trophoblastic tumor (PSTT). (A, B) Histology shows mostly intermediate placental site trophoblastic cell proliferation and infiltration into the myometrium. (C) Tumor cells show moderate cytotrophic atypia and have an increased Ki-67 index (>20%). Tumor cells are also negative for p63 (D), which excludes a diagnosis of epithelioid trophoblastic tumor; are strongly and diffusely positive for human placental lactogen (E) and pan-cytokeratin (G); and are diffusely positive for hCG (F) and inhibin (H). CK, cytokeratin; hPL, human placental lactogen; INH, inhibin.

hypertension, hyperthyroidism, and theca lutein cysts are not often seen. Presenting hCG levels are higher than 100,000 mIU/mL in only 10% of patients (70–72).

Diagnosis

Ultrasonography is the primary means of preoperative diagnosis of molar pregnancy, and its introduction has made diagnosis

at much earlier stages possible (5,73–75). Ultrasound not only provides information on the type of molar pregnancy, but also determines involvement of the endometrial cavity or myometrium, assesses the risk of uterine perforation, and detects theca lutein cysts and vaginal metastases. The diffuse hydropic swelling of the chorionic villi in complete molar pregnancy is seen as a characteristic vesicular “snowstorm” pattern on ultrasound, with many holes within the placenta and the absence of a fetus (Fig. 27.9). However, as this pattern is also seen in women with

FIGURE 27.8. Epithelioid trophoblastic tumor. Tumor cell proliferation in sheets (*upper left*) or cords (*upper right*), and myometrial invasion (*lower left*). Tumor cells stain positive for p63.

missed abortion, hematometra, or uterine fibroids ultrasound diagnosis alone is not very specific. When ultrasound diagnosis is combined with elevated hCG and the absence of fetal heartbeat, molar pregnancy is the most likely diagnosis. For partial moles, ultrasonography can detect focal cystic spaces in the placental and the enlarged gestational sac (75). Ultrasound may show the snowstorm pattern and a viable fetus, which may also indicate threatened abortion, fibroid uterus, or twin gestation with a single missed abortion and a complete mole. Partial mole can be confirmed with chorionic villus sampling that shows triploidy.

The most accurate disease-specific marker of GTD is hCG, which is produced by hydatidiform moles and CCA and can be measured quantitatively in the blood and urine. Placental hCG is a glycoprotein of two subunits, a common α subunit that is similar to the α subunit of pituitary hCG and a placenta-specific β subunit. In a normal pregnancy, hCG is essential for maintaining placental vascular supply (76). As pregnancy progresses, hCG is secreted by syncytiotrophoblasts, increasing to approximately 60,000 mIU/mL at 10 weeks and then declining to a range of values around 12,000 mIU/mL through the remainder of the pregnancy (77). hCG molecules secreted by trophoblast-derived moles and GTN are more heterogeneous than in a normal pregnancy, with transformation of the trophoblast resulting in fragmentation of the hCG molecule, and several forms of hCG are present, including hyperglycosylated,

FIGURE 27.9. Ultrasound of complete hydatidiform mole. The characteristic vesicular “snowstorm” pattern of multiple echoes, appearing as holes within the placenta. No fetus is present.

nicked, C-terminal truncated β subunit, free β subunit, nicked free β subunit, and free α subunit (78). Normally, hyperglycosylated hCG is produced by cytotrophoblasts early in gestation and acts as an autocrine regulator of trophoblast invasion of the implantation site and establishment of the fetomaternal circulation. Hyperglycosylated β subunit is produced by GTN lesions and promotes the growth and invasion of the malignant trophoblasts (79).

It is, therefore, essential that quantitative assays used to diagnose or follow up GTD detect all forms of the hCG protein and its degradation products. In one study, Cole et al., compared several commercially available hCG tests and found significant variations in assay results related to differences in recognition of hCG variants (80). The most common hCG assay is a monoclonal antibody sandwich assay (81). Complete hydatidiform moles present with markedly elevated hCG, with half of patients having levels greater than 100,000 mIU/mL (82,83). Because hCG levels in a normal pregnancy are highest at the end of the first trimester, hCG measurements need to be taken at several times to differentiate a complete molar pregnancy from a normal gestation, multiple gestation, or pregnancy complicated by diseases that are associated with an enlarged placenta. By contrast, hCG levels greater than 100,000 mIU/mL are seen in only 10% of patients with partial moles (71,72).

Diagnosis of complete and partial moles may also include pathologic examination of curettage tissue; however, with the diagnosis of hydatidiform mole occurring earlier in gestation, histologic analysis can be challenging (84,85). Cytogenetic analysis can differentiate between complete mole (androgenetic diploidy), partial mole (diandritic triploidy), and hydropic abortus (biparental diploidy). A hydropic abortus can contain enlarged villi, but lacks proliferating trophoblast (57). Immunohistochemical analysis may also help to confirm a diagnosis of molar pregnancy; specifically, p57kip2 expression can differentiate between complete and partial hydatidiform moles (Table 27.2) (86–90). This protein is paternally imprinted and maternally expressed; therefore, the villous cytotrophoblast cells in complete moles, which lack maternal chromosomes, will stain negative for p57kip2, whereas partial moles and hydropic abortus will stain positive. Fluorescence in situ hybridization can be used to distinguish between p57kip2-positive partial moles (triploid) and hydropic abortus (diploid) (91). *PHLDA2* is another maternally imprinted gene that can be used to identify partial moles (92).

False-Positive hCG Tests

hCG measurements are a critical diagnostic tool for GTD, but some assays may produce false-positive or “phantom” hCG results (93). False-positive hCG tests, some as high as 800 mIU/mL, can lead to unnecessary surgery and chemotherapy in healthy patients (94). These false-positive results are due to the presence of nonspecific heterophilic antibodies that mimic hCG and can interfere with the hCG sandwich assay. These antibodies are present in 3% to 4% of healthy people. Because the antibody does not pass into the urine, false-positive hCG test results can be identified by determining hCG levels in the urine. In addition, serial dilution of the serum sample would not show a decrease in the detected antibody.

Luteinizing hormone (LH) can also cross-react with hCG assays, leading to falsely elevated hCG in women with elevated pituitary FSH, LH, or hCG. hCG normally increases with age, and perimenopausal and postmenopausal women may have low-level hCG test results. To determine whether the hCG detected in the serum is from the pituitary, women may be given oral contraceptive to suppress LH, followed by simultaneous measurement of LH and hCG (95,96).

Treatment

Suction evacuation and curettage is the preferred treatment for hydatidiform mole in patients who wish to preserve their fertility (Table 27.5) (97,98). Patients should undergo a preoperative evaluation including vital signs, laboratory tests, and electrocardiogram to identify any medical complications, such as anemia, preeclampsia, and hyperthyroidism. The patient’s blood type and hCG levels should also be measured preoperatively. If the patient is hemodynamically stable, the type of molar evacuation procedure can be selected (99,100). If the uterus is greater than 12-week size, ultrasound monitoring should be used to prevent uterine perforation and ensure complete removal of the molar tissue. Suction evacuation and curettage is performed under anesthesia, and the cervix is dilated to allow passage of a 12- to 14-mm suction cannula into the lower uterine segment. The cannula is rotated to remove the intrauterine contents. Intravenous oxytocin should be started at the onset of the procedure and continued postoperatively for several hours to enhance uterine contraction. Rh-negative patients will also need to receive Rh immunoglobulin during evacuation because the Rh D factor is expressed by trophoblastic cells (99,100). Gentle sharp curettage should be applied after suction evacuation. At least 2 units of blood should be available because of the risk of bleeding, which increases with uterine size. Postoperative respiratory distress may occur due to trophoblastic embolization, excessive fluid resuscitation, or massive oxytocin infusion. Attention to blood and crystalloid replacement reduces the risk of pulmonary complications, though all patients should be monitored with a pulse oximeter for at least 2 hours after surgery. Patient outcomes can be improved with the judicious use of equipment, ready access to blood products, careful monitoring during the procedure, and anticipation and treatment of complications.

For patients who have completed childbearing and do not wish to preserve their fertility, hysterectomy may be performed as an alternative to suction evacuation and curettage (Fig. 27.10). Hysterectomy removes the risk of local myometrial invasion, and focal disease can be ruled out in patients with

Table 27.5 Evacuation of Hydatidiform Mole

Preoperative evaluation and preparation

1. Chest X-ray
2. Complete blood count
3. Electrolytes
4. Baseline oxygen saturation
5. Type and cross 2 units of blood
6. Set up Rho (D) immunoglobulin (RhoGAM) if patient is Rh-negative

Surgical procedure (with ultrasound guidance if uterus is >12 wk size)

1. Premedication and paracervical anesthesia
2. Dilatation
3. Suction curettage—leave cannula at lower uterine segment until majority of molar tissue has been removed
4. Begin intravenous oxytocin infusion
5. Gentle sharp curettage

Postevacuation

1. Monitor respiratory status and uterine bleeding for at least 2 h
2. Give RhoGAM if Rh-negative
3. Prescribe contraceptive
4. Follow hCG levels every 2 wk until 2 consecutive normal results, then every month for 6 mo and every 3 mo twice

hCG, human chorionic gonadotropin.

FIGURE 27.10. In selected patients, hysterectomy may decrease the likelihood of postmolar GTN. This photograph shows a 16-week size uterus filled with complete hydatidiform mole.

persistent GTD. The high cost of this procedure and the risk of complications should limit the use of hysterectomy to those patients at high risk of postmolar GTD, including women over the age of 40, greater than gestational date uterine size, theca lutein cysts greater than 6 cm, hCG greater than 100,000 mIU/mL, and medical complications of pregnancy. However, metastatic disease may still be present after hysterectomy, with a 3% to 5% risk of postmolar GTN, and patients should be followed up with serial hCG testing (97).

Medical induction of labor and hysterotomy are not recommended, because of the increased risk of maternal morbidity, including blood loss, incomplete evacuation requiring surgical intervention, and the need for cesarean delivery in subsequent pregnancies. This approach also increases the risk of trophoblastic dissemination and development of postmolar GTN requiring chemotherapy (98).

Use of prophylactic chemotherapy—either methotrexate or actinomycin D—at the time of evacuation or immediately afterwards can reduce the risk of postmolar GTN from 15%–20% to 3%–8%. However, this approach exposes patients to chemotherapeutic toxicity but benefits only a small number of patients. Because all patients who are found to have persistent postmolar GTD with serial hCG testing can be cured with chemotherapy, the use of prophylactic chemotherapy should be limited to those patients who have a greater than normal risk of postmolar GTN or who are less likely to comply with serial hCG testing during follow-up (101–103).

Molar Pregnancy and Coexisting Fetus

Twin pregnancies of a complete mole and normal fetus occur approximately once in every 22,000 to 100,000 pregnancies and may be difficult to distinguish from partial mole. Ultrasound can usually differentiate between these two scenarios, though cytogenetics may help distinguish a normal viable fetus from a triploid nonviable fetus in a partial mole. Patients with a twin normal/complete mole pregnancy are at higher risk of hemorrhage and other complications as well as a higher risk of persistent GTD. Although suction evacuation and curettage are recommended to terminate the pregnancy, 40% of these pregnancies will result in a normal viable fetus if left untreated (104–106).

Follow-Up

Clinical findings of successful evacuation include prompt uterine involution, ovarian cyst regression, and cessation of bleeding.

Definitive follow-up after molar evacuation requires serial serum quantitative hCG measurements every 1 to 2 weeks until 3 consecutive normal tests, and then every 3 months for 6 months to 1 year after normalization. More than 50% of patients will achieve a normal hCG within 2 months of evacuation. Contraception is recommended for 6 months after the first normal hCG result so that any postmolar elevation in hCG that is detected can be distinguished from the hCG rise that occurs in a normal pregnancy. Oral contraceptives are preferred because they suppress LH and remove any interference with hCG assay measurements. Studies have shown that oral contraceptives do not increase the risk of postmolar GTN (107–109).

Prognosis

Disease-free survival and fertility is achieved in 80% of patients with hydatidiform mole, and compliant patients who are followed closely with serial hCG measurements are more likely to achieve cure. High-risk postmolar disease is more often seen after a term pregnancy or in patients who were lost to follow-up. There is a 1% to 2% increased risk of developing a second complete molar pregnancy (110), and a much lower risk of a second partial molar pregnancy (111).

Quiescent GTD

Some women with a history of GTD or spontaneous abortion may have a consistently low level of hCG (<200 mIU/mL for at least 3 months) but no detectable disease. There is also no hyperglycosylated hCG, which would indicate cytotrophoblastic invasion. This “quiescent GTD” does not respond to either surgery or chemotherapy. It is believed that the hCG being detected in these patients is produced by dispersed foci or individual slow-growing syncytiotrophoblast cells with no invasive potential in the absence of cytotrophoblast or intermediate trophoblast. Approximately one-quarter of patients with quiescent GTD go on to develop active GTN, with detectable increases in both hCG and hyperglycosylated hCG levels (112,113). These patients may secrete increased hyperglycosylated hCG within 5 years of the initial pregnancy event, weeks to months before a detectable rise in hCG or clinical evidence of GTN (114). To diagnose quiescent GTD, false-positive hCG testing should be ruled out and the patient examined for any evidence of disease. Patients should be monitored closely with periodic hCG testing and should avoid pregnancy (95). Chemotherapy and surgery

should be avoided unless a diagnosis of GTN can be made, based on either a sustained rise in hCG or the appearance of disease.

Pregnancy after Hydatidiform Mole

All women with a history of molar pregnancy have a higher risk of developing malignant disease in a subsequent pregnancy. After molar evacuation, women should wait at least 6 months from the time of hCG normalization to become pregnant. For all future pregnancies, pathologic examination of the placenta and other products of conception and measurement of hCG 6-weeks postpartum are recommended.

Persistent GTD/Postmolar GTN

Postmolar invasive mole or CCA occurs after 15% to 20% of complete and 1% to 5% of partial molar pregnancies, and invasive mole is seen more frequently (85% to 90%) than CCA (10% to 15%) (51,52,58,99,115–120). Approximately, half of all cases of CCA arise from a prior molar pregnancy, but only 2% to 3% of all hydatidiform moles will progress to CCA (121). A diagnosis of CCA after a partial mole has been reported as single cases in the literature (51,52,58,122–126). Of those with invasive mole, 15% will have metastatic disease to the lungs or vagina. Most PSTTs and ETTs arise after nonmolar pregnancies, sometimes years after the pregnancy event (64,127,128).

The likelihood of persistent GTD after a molar pregnancy is higher in women who initially presented with marked trophoblastic growth, as indicated by hCG levels greater than 100,000 mIU/mL, excessive uterine size (>20 weeks), and theca lutein cysts greater than 6 cm in diameter. Women who have at least one of these risk factors have a 40% chance of developing postmolar GTN, compared with a 4% risk in those with none of these factors. Other risk factors for postmolar GTN include age greater than 40 years, repeat molar pregnancy, aneuploidy mole, and medical complications of molar pregnancy, such as toxemia, hyperthyroidism, and trophoblastic embolization (99).

At the molecular level, studies have found that women who will develop postmolar disease are more likely to show telomerase activity (129). Conversely, apoptotic activity measured by various techniques is higher in hydatidiform moles that spontaneously regress versus those that go on to develop postmolar GTN (130,131). Other studies have found that hydatidiform moles that are more likely to progress to malignant disease have lower expression of the anti-apoptotic gene *Mcl-1* (132), ferritin light polypeptide (FTL), and IGFBP-1 (133).

Repeat curettage for persistent GTD is not recommended, except in patients with excessive uterine bleeding and intracavitary molar tissue on radiologic scans. In one retrospective study, although 9.4% of women who underwent repeat curettage avoided chemotherapy, there was a 2.4% risk of uterine perforation (134). Thus, the small benefit of repeat curettage in achieving remission or improving treatment outcomes does not outweigh the risk of uterine perforation and hemorrhage (134–137). A prospective phase II Gynecologic Oncology Group (GOG) trial is under way that will determine the utility of second curettage and whether benefit and risk vary with the depth of uterine infiltration (GOG 242, NCT00521118).

GTN, either invasive mole or CCA, presents as irregular bleeding after evacuation of a hydatidiform mole (usually a complete mole). Invasive mole is diagnosed clinically rather than pathologically, with persistent hCG elevation after molar evacuation. CCA occurs in association with any pregnancy event, with approximately 25% of cases occurring after abortion or tubal pregnancy, 25% after term or preterm gestation, and 50% after a molar pregnancy. Sometimes, a metastatic vaginal lesion may be disrupted during pelvic examination, which can lead to uncontrolled vaginal bleeding. Women with postmolar GTN may also present with an enlarged, irregular uterus and bilateral ovarian enlargement. There are no signs or symptoms that differentiate between postmolar GTN and GTN arising after a nonmolar pregnancy event, as these symptoms are related to the invasion and metastasis of the tumor. GTN should be considered in patients who present with postpartum bleeding and subinvolution, although other causes include endomyometritis, tumors in other organ systems, or another pregnancy. Uterine perforation and metastases can cause abdominal pain, hemoptysis, melena, or increased intracranial pressure that leads to headaches, seizures, or hemiplegia. Symptoms suggesting pulmonary involvement include dyspnea, cough, and chest pain (121), and early respiratory failure requiring mechanical ventilation may develop. A diagnosis of GTN should be considered for any women of reproductive age who presents with pulmonary symptoms. Symptoms of brain metastases include vomiting, seizures, headache, hemiparesis, and speech and visual disturbances. Liver and gastrointestinal metastases are rare, and usually are seen with simultaneous lung or brain involvement; these patients have the lowest survival rate (138). PSTT and ETT often present with irregular vaginal bleeding and an enlarged uterus, with hCG levels from normal to 1,000 mIU/mL, sometimes years after a previous pregnancy. PSTT may also present with liver, lung, or brain metastases, or complications such as neoplastic nephrotic syndrome. The risk of metastatic PSTT is higher in patients with more than 5 mitoses per 10 high-power fields.

Diagnosis

The International Federation of Gynecology and Obstetrics (FIGO) defined a set of criteria for diagnosing persistent GTD in 2002 (Table 27.6) (139). Postmolar GTN is usually diagnosed when hCG levels plateau or rise during follow-up after molar evacuation, without histologic diagnosis. An hCG plateau is defined as a less than 10% decline in 4 measurements taken over 3 weeks. A rise is defined as a greater than 20% increase in 3 measurements taken over 2 weeks. The presence of elevated hCG in addition to metastases usually indicates CCA, whereas with PSTT and ETT, serum hCG levels are only slightly elevated, making differential diagnosis particularly challenging (64,127,128). The free hCG β subunit may be the best biomarker for diagnosing PSTT, and the β core fragment for ETT (38,76). Although a diagnosis of GTN can be confirmed pathologically by examination of the curettage, or hysterectomy specimens, or the placenta, or biopsy of metastatic lesions, the risk of hemorrhage is too high, and biopsy of vaginal lesions should be avoided (140).

For any patient with suspected or established GTN, a metastatic workup and evaluation of risk factors is performed (3,32,110,141). A complete history, physical examination, and laboratory tests (including complete blood cell count, coagulation study, serum chemistries, blood type and antibody screening, and quantitative serum hCG level) should be taken. Radiologic studies should start with a chest X-ray; if abnormal, a CT or MRI of the chest should be performed to detect pulmonary metastases. CT scans of the abdomen and pelvis and MRI of the brain should also be performed. The vast majority of patients with brain involvement (94%) have associated lung metastases; conversely, 20% of patients with lung metastases also have brain metastases. Brain metastases tend to appear in

GESTATIONAL TROPHOBLASTIC NEOPLASIA

Clinical Presentation

The clinical presentation of GTN depends on the pregnancy event, the extent of disease, and histopathology. Postmolar

Table 27.6 FIGO 2000 Criteria for Diagnosis of Persistent GTD/Postmolar GTN

hCG plateau lasting for 4 measurements over a period of at least 3 wk (days 1, 7, 14, and 21)
Rise in hCG of 10% or more for 3 measurements over at least 2 wk (days 1, 7, and 14)
Persistence of elevated hCG 6 mo after mole evacuation
Presence of a histologic diagnosis of CCA

hCG, human chorionic gonadotropin; CCA, choriocarcinoma.

the parietal lobe, and on the right side of the brain (Fig. 27.11). If the physical examination and the chest X-ray are normal and there are no symptoms of metastasis, other sites of metastasis are rarely present. To detect brain involvement, hCG testing of the cerebrospinal fluid (CSF) may be helpful; a serum/CSF hCG ratio of less than 60:1 is a sensitive marker of CNS metastasis (142), although false positives can occur if measurements are taken when hCG levels are falling. Pelvic ultrasound and MRI may be useful to detect extensive uterine disease and identify patients who may benefit from hysterectomy. Biopsy of metastases is not recommended, as the associated risks of biopsy outweigh the benefits of confirming a diagnosis of metastatic disease.

Staging and Risk Scoring

In 2002, FIGO adopted a combined anatomic staging system and a modified version of the WHO risk factor scoring system for GTN (Tables 27.7 and 27.8) (143). The FIGO stage is designated by a Roman numeral and is followed by the modified WHO score designated by an Arabic numeral, separated by a colon. The risk score takes into account 8 criteria, each of which is given a score from 0 to 4. Treatment of GTN is based on the classification of patients into risk groups defined by the stage and risk factor scoring system (144). The FIGO system is essential for selecting initial therapy for patients with GTN that will ensure the best possible outcomes with the fewest side effects. A recent study found that most patients classified as low-risk but who have an initial level of hCG greater than 400,000 mIU/

mL will fail their initial chemotherapy, suggesting that perhaps these patients would benefit from multiagent chemotherapy (145). Patients with hCG levels between 100,000 mIU/mL and 400,000 mIU/mL will either respond to a single-agent regimen or require a change in regimen to achieve cure. Note that this staging and risk factor scoring system does not apply to either PSTT or ETT.

Recently, Cole et al. described a form of “minimally-aggressive GTN” that is chemorefractory, has a slow growth rate, and can be detected by low levels of hyperglycosylated hCG (<40% of total hCG) or by an hCG doubling rate greater than 2 weeks (146). Thus far, data are available on 24 patients with this type of GTN, who were treated successfully using a protocol that delays chemotherapy until hCG levels exceed 3,000 mIU/mL.

Management

The cure rate for high risk GTN—most commonly CCA—is currently greater than 90%, and for low-risk disease is approaching 100%, primarily due to the inherent sensitivity of trophoblastic

Table 27.9 Chemotherapy for Low-Risk Gestational Trophoblastic Neoplasia	
Regimen	Primary Remission Rate (%)
MTX 0.4 mg/kg (max 25 mg)/day IV or IM for 5 d; repeat every 2 wk	87–93
MTX 30–50 mg/m ² IM weekly	49–74
MTX 1 mg/kg IM days 1, 3, 5, and 7; folinic acid 0.1 mg/kg IM days 2, 4, 6, and 8; repeat every 15–18 d or as needed	74–90
MTX 100 mg/m ² IVP, then 200 mg/m ² in 500 mL D5W over 12 h; folinic acid 15 mg IM or PO every 12 h for 4 doses beginning 24 h after start of MTX; repeat every 18 d or as needed	69–90
Act D 10–13 mg/kg IV every day for 5 d; repeat every 2 wk	77–94
Act D 1.25 mg/m ² IV every 2 wk (max 2 mg/day)	69–90
Alternating MTX 0.4 mg/kg (max 25 mg)/day IV or IM for 5 d and Act D 10–13 mg/kg IV every day for 5 d	100

Act D, actinomycin D; D5W, dextrose 5% in water; IM, intramuscular; IV, intravenous; IVP, intravenous push; MTX, methotrexate; PO, by mouth.

neoplasms to chemotherapy, the effective use of hCG as a marker of early disease, the referral of patients to specialized centers, the identification of predictive factors of treatment response that has permitted individualization of therapy, and the use of combined surgery, radiation, and chemotherapy in the highest risk patients. Management of PSTT and ETT is more challenging because these neoplasms are often resistant to chemotherapy and hCG level is not a strong marker of these diseases.

Low-Risk GTN

Patients in the low-risk group are those with Stage I disease (nonmetastatic) or Stage II and III disease (metastatic) with a risk score of less than 7. These patients should undergo single-agent chemotherapy with either methotrexate or actinomycin D (147,148), which has achieved survival rates approaching 100%. Invasive mole is often treated with chemotherapy without a pathologic diagnosis (121). There are several different chemotherapy protocols for low-risk nonmetastatic GTN that have produced comparable results in nonrandomized, retrospective studies (Table 27.9). Taken together, these studies suggest that the 5-day methotrexate or actinomycin D protocols or the 8-day methotrexate-folinic acid protocol are more effective than either weekly intramuscular (IM) or intermittent intravenous (IV) infusion of methotrexate or the biweekly single-dose actinomycin D protocols. Remission rates with each protocol vary due to differences in drug doses, schedules, routes of administration, and patient factors. These studies also found that initial chemotherapy resistance is associated with older age, higher hCG, nonmolar antecedent pregnancy, histopathologic diagnosis of CCA, presence of metastases, and higher FIGO score. Common side effects of these regimens are stomatitis, mucositis of the GI tract, pleuritis, conjunctivitis, and skin rash.

Chemotherapy is continued until hCG values have returned to normal, and at least 1 course is administered after the first normal hCG level is achieved. A recent retrospective study compared relapse rates in women from the UK and the Netherlands with low-risk disease who were treated with methotrexate

Table 27.10 Treatment of low-risk GTN at the Brewer Trophoblastic Disease Center			
Regimens: MTX 0.4 mg/kg (max 25 mg)/day IV for 5 d, repeat every 2 wk; Act D 10–13 mg/kg IV every day for 5 d, repeat every 2 wk			
	Complete Remission Rate to Initial Single-Agent MTX	Required Multiagent Chemotherapy or Surgery	Cured
Lurain et al. (1995) (1962–1990) (150)	89.3% (226/253 nonmetastatic, low-risk GTN)	2%	100%
Roberts and Lurain (1996) (1962–1992) (182)	65.6% (40/61 metastatic, low-risk GTN)	3%	100%
Chapman-Davis et al. (2009) (1979–2009) (183)	81% (291/360 FIGO low-risk GTN ^a)	6%	100%

^aStage I disease (nonmetastatic) and Stage II and III disease (metastatic), risk score <7.

alternating with folinic acid (149). A greater number of patients relapsed with only two consolidation courses than those who received three consolidation courses after reaching the institutional normal hCG value of greater than 5 mIU/mL. If hCG levels plateau at a point above normal during treatment or if toxicity limits the ability to administer the chosen regimen, chemotherapy is changed to an alternative single-agent regimen. Multiagent chemotherapy is indicated in the event of a significant elevation in hCG, development of metastases, or resistance to sequential single-agent chemotherapy. While there are differences in primary remission rates with each of the chemotherapy protocols, the cure rate remains high and most patients are able to preserve their fertility.

The John I. Brewer Trophoblastic Disease Center reviewed 30 years' of experience treating GTN to determine the most effective therapy, evaluate toxicity, and identify the factors associated with treatment resistance (Table 27.10) (150). Of 253 patients who received initial therapy of single-agent methotrexate (0.4 mg/kg, maximum 25 mg) as an IV push for 5 days every 2 weeks, only 5 required subsequent multiagent chemotherapy (90% complete response), and all patients achieved permanent remission. Only 12 patients experienced significant side effects with methotrexate, most commonly stomatitis, leading to a change in therapy to another agent, and no life-threatening toxicities were noted. Resistance to the initial single-agent methotrexate regimen was associated with high pretreatment hCG, nonmolar antecedent pregnancy, and clinicopathologic diagnosis of CCA. These findings are consistent with those of other centers and suggest that the most effective treatment protocol for low-risk nonmetastatic GTN is methotrexate 0.4 mg/kg (maximum total dose 25 mg) IM or IV push given once daily for 5 days every other week (150–152).

Other regimens for low-risk nonmetastatic disease include methotrexate 1.0 to 1.5 mg/kg given every other day alternating with folinic acid (0.1 to 0.15 mg/kg) for 8 days, with at least 1 week between treatments. Though this regimen is associated with lower toxicity than the 5-day regimen, it is inconvenient and a greater number of patients require a change in chemotherapy to achieve remission (153–159). Yet another modification of a methotrexate regimen is a high-dose (100 mg/m²) IV push followed by a 12-hour infusion at 200 mg/m² with folinic acid

(160); with this regimen, the interval between doses is dependent on the posttreatment hCG level. However, this treatment often requires second-line therapy (159–162). Finally, a regimen of weekly IM doses of methotrexate 30 to 50 mg/m² has the lowest complete response rate, and although it is more convenient, less costly, and less toxic, it is not appropriate for treating GTN (163–165).

Two retrospective case studies compared 5-day IM methotrexate and 8-day methotrexate-folinic acid protocols in patients with low-risk nonmetastatic GTN; one study found that there was no difference in remission rates (76%) (156), and the other reported lower remission rates in patients receiving methotrexate-folinic acid (72%) than in patients receiving methotrexate alone (92%) (166). Gleeson et al. subsequently reported a 69% primary remission rate in patients with nonmetastatic postmolar GTN treated with weekly methotrexate alone and a 75% remission rate with methotrexate-folinic acid (167).

As an alternative to methotrexate, actinomycin D may be given as an IV push of 10 to 12 µg/kg daily for 5 days every other week or as a single 1.25 mg/m² IV dose every week (168–172). The primary remission rate for patients with nonmetastatic postmolar GTN was 88% for 5-day actinomycin D and 78% for pulsed actinomycin D (173). However, actinomycin D is more often used as a second-line therapy in patients with methotrexate resistance or with contraindications to methotrexate, as it is associated with higher toxicity, particularly alopecia, and produces local tissue injury in cases of IV extraversion (174).

Several studies have compared weekly methotrexate and biweekly actinomycin D regimens for treatment of low-risk, nonmetastatic GTN. Across three randomized clinical trials, IM methotrexate was associated with lower primary complete response rates (49% to 53%) than pulsed actinomycin D (69% to 90%) (175–177). In the phase III GOG study (177), there was a higher complete response for biweekly IV actinomycin D than for weekly IM methotrexate (70% vs. 53%; $p = 0.01$), and in patients with lower risk scores (<5), the response rate was 73% and 58%, respectively ($p = 0.03$). Both regimens were less effective in patients with risk scores of 5 or 6 or if the diagnosis was CCA (complete response: 42% and 9%, respectively). Actinomycin D was associated with a high incidence of grade 1 alopecia and grade 1 nausea (177). In another randomized study of patients with stage I nonmetastatic GTN, complete remission was achieved in 74% of women who received methotrexate-folinic acid and in 100% of women who received 5-day actinomycin D (178). In a retrospective study of patients with low-risk, mostly nonmetastatic GTN, Abrao et al. reported no significant difference in the complete remission rates with 5-day regimens of methotrexate or actinomycin D or combination therapy (69%, 61%, and 79%, respectively); however, the incidence of side effects was much higher in patients receiving the combination therapy than either single-agent regimen (179).

For patients with low-risk metastatic GTN (Stage II or III, score <7), single-agent chemotherapy with multi-day dosing of either methotrexate or actinomycin D is appropriate; however, the biweekly actinomycin D protocols used for nonmetastatic disease should not be used in these patients (Table 27.9). Three specialized trophoblastic disease centers in the U.S. have reported remission rates of 48% to 67% in patients with low-risk, metastatic GTN with single-agent chemotherapy, with 1% to 14% of patients requiring multi-agent therapy after failure of single-agent therapy with or without surgery (Table 27.10) (180–182). In this group of patients, resistance to single-agent therapy was associated with pretreatment hCG levels >100,000 mIU/mL, age older than 35 years, a FIGO score of 4, and the presence of large vaginal metastases.

At the Brewer Trophoblastic Disease Center, we recently examined risk factors for developing resistance to initial methotrexate therapy in 358 patients with low-risk GTN between 1979 and 2009 (Table 27.10) (183). Patients initially received

methotrexate 0.4 mg/kg (max 25 mg) IV push daily for 5 days every 14 days. Actinomycin D 0.5 mg IV push daily for 5 days every 14 days was used in 64 patients who developed resistance or toxicity to initial methotrexate chemotherapy, and multiagent regimens were used in 20 patients for whom either single-agent chemotherapy failed. The complete response rate to initial methotrexate chemotherapy was 81%, and the complete response rate to actinomycin D as secondary therapy was 75% (94% overall complete response rate to sequential single-agent chemotherapy). The remaining patients achieved permanent remission with multi-agent chemotherapy with or without surgery. Resistance to initial methotrexate chemotherapy was associated with increasing FIGO score ($p < 0.0001$), clinicopathologic diagnosis of CCA ($p = 0.028$), higher pretreatment hCG ($p = 0.001$), and presence of metastatic disease ($p = 0.018$).

In general, primary treatment failure occurs in 10% to 30% of patients with low-risk GTN, and in 30% to 50% of patients with low-risk, metastatic disease. Most patients who are resistant to the initial chemotherapy will be placed into remission after changing to another single-agent chemotherapy. Patients with low-risk disease will rarely require multiagent chemotherapy, and approximately 15% of patients with low-risk, metastatic GTN will require multi-agent chemotherapy with or without surgery. The higher rate of failure of initial single-agent therapy in patients with higher FIGO scores has led some to propose an intermediate risk group of patients who have metastatic disease with scores of 5 or 6. Ideally, treatment failure should be identified as early as possible to limit patient exposure to ineffective chemotherapy cycles. Several groups have tried to determine an hCG cutoff value that can predict treatment resistance to allow prompt changes in treatment (184–186). One group found that a cutoff value of 737 mIU/mL was able to predict resistance to 8-day methotrexate with a specificity of 97.5% (186,187). If treatment change is necessary, the risk score is recalculated to determine the most appropriate second-line regimen.

In patients with low-risk GTN who do not wish to preserve their fertility, adjuvant hysterectomy may be performed with the initiation of chemotherapy to reduce the length of treatment required to achieve remission (188). Other indications for hysterectomy in low-risk GTN include persistent, chemotherapy-resistant disease in the uterus or to treat uterine tumor hemorrhage.

High-Risk GTN

Chemotherapy

Patients in the high-risk group have metastatic GTN, either Stage IV disease or Stage II and III disease with a risk factor score greater than 7. These patients are treated more aggressively, with multiagent chemotherapy with or without adjuvant radiation or surgery (Table 27.11). With this approach, cure rates have reached 80% to 90%. Treatment delay or dose reduction due to side effects increases the likelihood of tumor resistance and treatment failure. Historically, a combination treatment of methotrexate, actinomycin D, and cyclophosphamide or chlorambucil (MAC) was used as first-line therapy for high-risk, metastatic GTN and achieved cure in 63% to 71% of patients (Table 27.12) (189,190). Over time, the chemotherapy regimen of choice shifted to a combination of cyclophosphamide, hydroxyurea, actinomycin D, methotrexate with folinic acid, vincristine, and doxorubicin (CHAMOCA) (Fig. 27.12). The primary remission rate in high-risk, metastatic GTN was reported to be 82% with this regimen (191). However, a subsequent randomized trial comparing MAC and CHAMOCA found that the primary remission rate and the cure rate were inferior for CHAMOCA, which also had a more toxic side effect profile (192). The addition of etoposide to a regimen containing high-dose methotrexate with folinic acid, actinomycin D,

FIGURE 27.12. Evolution of chemotherapy for GTN at the John I. Brewer Trophoblastic Disease Center. Chemotherapy regimens are shown for low-risk disease, as well as the first-line therapy and subsequent regimens for recurrent or resistant high-risk disease. For PSTT, chemotherapy may be used in patients with metastatic disease and in patients with nonmetastatic disease and poor prognostic factors.

Table 27.11 EMA-CO Chemotherapy for High-Risk Gestational Trophoblastic Neoplasia

Treatment Day	Regimen	
1	Etoposide	100 mg/m ² IV over 30 min
	Act D	0.5 mg IVP
	MTX	100 mg/m ² IVP, then 200 mg/m ² in 500 mL D5W over 12 h
2	Etoposide	100 mg/m ² IV over 30 min
	Act D	0.5 mg IVP
	Folinic acid	15 mg IM or PO every 12 h for 4 doses starting 24 h after start of MTX (on day 1)
8	Cyclophosphamide	600 mg/m ² IV
	Vincristine	1.0 mg/m ² IVP

Cycle repeats every 2 weeks (i.e., days 15, 16, and 22).

IV, intravenous; Act D, actinomycin D; IVP, intravenous push; MTX, methotrexate; D5W, dextrose 5% in water; IM, intramuscular; PO, by mouth.

and vincristine (EMA-CO) improved both primary remission and survival rates in patients with high-risk GTN (Table 27.12) (193,194). The efficacy of the EMA-CO regimen for high-risk GTN has been reported to achieve complete response rates between 71% and 78% and long-term survival rates of 85% to 94% (195–202). In our study series (199,200,203), we reported complete response rates of 76%, 67%, and 54% and overall survival rates of 92%, 93%, and 92% with EMA-CO treatment. Deaths occurred only in patients with FIGO stage IV disease with scores greater than 12, and no treatment-related deaths or severe toxicities were seen. Neutropenia was rare, though alopecia and anemia were common, and mild paresthesia and

stomatitis occurred in 20% of patients. Some centers may use the EMA-EP regimen for patients with scores greater than 12. In the United Kingdom, patients with brain metastases are treated with intrathecal methotrexate rather than whole-brain radiotherapy (204).

Though aggressive multiagent therapy is associated with high levels of toxicity, single-agent therapy is not appropriate for high-risk patients, as the success rate of secondary chemotherapy after failure of single-agent therapy is only 20% to 50%. Based on current evidence, EMA-CO is the initial treatment of choice for patients with high-risk, metastatic GTN. The regimen has high complete response rates and survival rates, as well as low toxicity that improves patient adherence to treatment and thus reduces the risk of drug resistance. Chemotherapy is continued for at least 2 to 3 courses after the first normal hCG level is achieved.

Radiation

For patients who present with brain metastases, whole brain radiation (3,000 cGy in 200 cGy fractions) or, in selected patients, surgical excision with stereotactic radiation, is indicated and is usually performed at the start of chemotherapy to lower the risk of hemorrhage (205,206). In these patients, the EMA-CO regimen is modified such that methotrexate is increased to 1 g/m² with 30 mg of folinic acid every 12 hours for 3 days, starting 32 hours after the start of infusion (207). Intrathecal and high-dose methotrexate may also be used in some centers. Patients are also treated with dexamethasone to decrease edema and phenytoin sodium to prevent seizure. During therapy, patients undergo serial CT scans or MRIs to monitor the lesions. Once a complete response has been achieved, hCG levels in the CSF should be measured, ideally by radioimmunoassay to detect low levels of protein. The plasma to CSF ratio of hCG should be less than 60. Patients with brain metastases have a cure rate of 50% to 80% depending on patient symptoms and the number, size, and location of brain lesions (204,208).

Surgery

Approximately 50% of patients with high-risk, metastatic GTN will require adjuvant surgical procedures, usually hysterectomy

and pulmonary resection for chemotherapy-resistant disease and to control hemorrhage and sepsis (209–220). Selected patients with focal disease may be candidates for partial lung, liver, or brain resection. Imaging with fluorodeoxyglucose PET, with CT for anatomic localization, may help with targeted surgery (221). For women with excessive vaginal bleeding, selective arterial embolization may be beneficial. We reviewed a series of 50 patients with high-risk GTN who were treated at the Brewer Trophoblastic Disease Center from 1986 through 2005 with EMA-CO as primary or secondary therapy. Twenty-four patients (48%) underwent 28 adjuvant surgical procedures, and 21 (87.5%) were cured. Fifteen of 17 patients who underwent hysterectomy; 4 of 5 patients who had resistant foci of CCA in the lung resected; all 4 patients who had suturing of the uterus, uterine artery embolization, small bowel resection, and salpingectomy for bleeding; and 1 patient who had uterine wedge resection for resistant CCA survived (213).

Second-Line/Salvage Therapy

Despite the use of multimodal primary therapy, approximately 30% of patients with high-risk GTN will have an incomplete response or will relapse from remission and will require secondary chemotherapy (222–225). Risk factors for relapse include the presence of multiple metastases to sites other than the lung and vagina and inadequate first-line chemotherapy. Salvage chemotherapy with the EMA-EP regimen, in which etoposide and cisplatin have been substituted for cyclophosphamide and vincristine in the EMA-CO regimen, is the most appropriate for patients who have not responded (plateaued low hCG levels) or experienced a relapse (re-elevation of hCG after a complete response) to first-line EMA-CO. This regimen is highly toxic and usually requires granulocyte colony-stimulating factor (G-CSF) support by the third cycle. Salvage chemotherapy combined with surgical excision of persistent tumor will result in cure for most of these high-risk patients (226–228). In patients who have developed resistance to methotrexate-containing protocols, drug combinations containing etoposide and platinum with bleomycin, ifosfamide, or paclitaxel have also been effective (222,229).

At the Brewer Trophoblastic Disease Center, we reported on 26 patients with persistent or relapsed high-risk GTN who received secondary platinum-based salvage chemotherapy. The overall survival was 61.5% (16/26). Of the 16 patients for whom primary therapy with methotrexate/actinomycin D-based chemotherapy without etoposide failed, 10 (63%) had complete clinical responses to bleomycin, etoposide, and cisplatin; etoposide, ifosfamide, and cisplatin; and ifosfamide, carboplatin, and etoposide; and 10 (63%) were cured. Of the 10 patients for whom primary therapy with EMA-CO failed, 9 (90%) had complete clinical responses to EMA-EP or bleomycin, etoposide, cisplatin, but only 6 (60%) subsequently achieved a lasting remission (222).

Most recently, we reviewed the effect of etoposide/platinum-based salvage therapy in 49 women (20 of whom were treated secondarily at our center) with high-risk GTN treated between 1986 and 2010 for whom initial multiagent therapy with EMA-CO had failed (Table 27.13) (228). Salvage therapy included etoposide and a platinum agent with methotrexate and actinomycin D (EMA-EP), bleomycin (BEP), ifosfamide (VIP, ICE) or paclitaxel (TP/TE). Of the 28 patients who had developed resistance to EMA-CO, 82% achieved lasting complete responses to salvage therapy. Three of four patients who received radiation therapy for brain metastases survived, and 82% of patients who required surgical procedures to remove metastases survived. High hCG level at the start of salvage therapy ($p < 0.001$), a higher number of metastatic sites ($p < 0.02$), and metastases to sites other than the lung and vagina ($p < 0.05$) were associated with lower survival in these patients. Patients with metastases in the brain, liver, and gastrointestinal tract have a 75%, 73%, and 50% survival rate, respectively (230).

Table 27.12 Treatment of High-Risk GTN at Brewer Trophoblastic Disease Center

Brewer (1968) (190)	MTX and/or Act D followed by MAC: 39% survival

PSTT and ETT

Because of the relative resistance of PSTT and ETT to chemotherapy and the high risk of lymphatic spread, hysterectomy with lymph node dissection is the recommended treatment. Prior to surgery, histologic diagnosis of PSTT with endometrial biopsy or curettage specimen should be confirmed with immunohistochemical staining for the presence of human placental lactogen and the absence of hCG. Chemotherapy may be used in patients with metastatic disease and in patients with non-metastatic disease and poor prognostic factors, including a long interval between last pregnancy and diagnosis (>2 years), deep

myometrial invasion, tumor necrosis, and mitotic count greater than 5/10 high-power fields (231,232). Though we do not know the optimal chemotherapy regimen for PSTT and ETT, the current treatment of choice is a platinum-containing regimen, such as EMA-EP or a paclitaxel/cisplatin–paclitaxel/etoposide (TP/TE) doublet. With hysterectomy and chemotherapy, the survival rate is approximately 100% for nonmetastatic disease and 50% to 60% for metastatic disease (233–235).

Reasons for Treatment Failure

We identified patients who were transferred to the Brewer Trophoblastic Disease Center after treatment failure elsewhere in order to determine the causes of treatment failure. We also compared our second-line treatment results from 1979 to 2006 with previous reports from 1962 to 1978 (Table 27.14) (236). The most common reasons for treatment failure for GTN were (1) use of single-agent chemotherapy for patients with high-risk disease; and (2) inappropriate use of weekly IM methotrexate chemotherapy for treatment of patients with metastatic disease, FIGO scores ≥ 7 , and/or non-postmolar CCA. Successful secondary GTN treatment in these patients improved from 59% during 1962 through 1978 to 93% during 1979 through 2006, most likely as a result of center experience and the use of more effective chemotherapy regimens. It is recommended that clinicians request advice from or referral for treatment to centers with expertise in management of GTN for patients who fail single-agent therapy for low-risk disease and for any patient with high-risk disease (237).

Follow-Up of GTN

After hCG has returned to normal levels and treatment has been completed, serum quantitative hCG levels should be obtained at 1-month intervals for 12 months. The risk of relapse is approximately 3% in the first year after completing therapy and drops to less than 1% thereafter. Physical examinations are performed at intervals of 6 to 12 months, and other testing is rarely indicated.

Pregnancy after GTN

Successful treatment of GTN with chemotherapy has allowed most women to preserve their fertility, despite exposure to drugs that are toxic to the ovary. Most women resume normal ovarian function after chemotherapy and exhibit no increase in infertility. Menopause may occur earlier, however (238). Contraception should be maintained during treatment and for 1 year after completion of chemotherapy, preferably using oral contraceptives, to allow for uninterrupted hCG follow-up and to permit the ovulation of eggs that may have been damaged by exposure to cytotoxic drugs.

Successful pregnancies have been reported after GTN, without an increased rate of abortion, stillbirth, congenital anomalies, prematurity, or major obstetric complications (22,239,240). There is no evidence for reactivation of disease with subsequent pregnancies, although patients who have had 1 trophoblastic disease episode have a 1% to 2% risk of a second GTD event, independent of previous chemotherapy. Therefore, pelvic ultrasound is recommended in the first trimester of any post-GTN pregnancy to confirm a normal gestation. The products of conception or placentas from future pregnancies should also be carefully examined histopathologically, and a serum quantitative hCG level should be determined 6 weeks after any pregnancy.

Table 27.14 Overall Results of Treatment of GTN at the Brewer Center 1962–2006

Treatment Site/Dates	Number	Survival
Primarily at Brewer Center	740	702 (95%) ^a

Source: Adapted from Lurain JR, Hoekstra AV, Schink JC. Results of treatment of patients with gestational trophoblastic neoplasia referred to the Brewer Trophoblastic Disease Center after failure of treatment elsewhere (1979–2006). *J Reprod Med.* 2008;53(7):535–540, with permission.

Risk of Secondary Malignancies

Because of the relatively short exposure of patients with GTN to intermittent schedules of methotrexate and actinomycin D and the infrequent use of alkylating agents, there are few reports of increased susceptibility to the development of other malignancies. However, increased use of etoposide-containing drug combinations for treatment of GTN has led to an increased risk of secondary malignancies, including acute myelogenous leukemia, colon cancer, melanoma, and breast cancer (241). Because of this, and an association with alopecia and severe nausea, the use of etoposide-containing regimens is limited to patients with high-risk disease.

CONCLUSIONS

The more widespread use of ultrasound to evaluate patients who present with vaginal bleeding has led to earlier diagnosis of hydatidiform mole. While hCG is a disease-specific marker for complete molar pregnancy, levels vary widely in individual patients, and those who are diagnosed with earlier stage disease may not show highly elevated hCG. The majority of patients with molar pregnancy are successfully treated with suction evacuation and curettage, and the risk of a second molar pregnancy or development of postmolar neoplasia is low.

Cure rates for both nonmetastatic and low-risk, metastatic GTN should approach 100% with the use of initial single-agent methotrexate or actinomycin D chemotherapy. Approximately 20% of low-risk patients will develop resistance to the initial chemotherapeutic agent, but 90% will be cured by the use of sequential single-agent chemotherapy. Eventually, approximately 10% of patients will require multiagent chemotherapy with or without surgery to achieve remission. With aggressive, multimodality therapy—EMA-CO with adjuvant radiotherapy or surgery as indicated—cure rates for high-risk GTN have reached 80% to 90%. Though one-third of high-risk patients fail first-line therapy or experience a relapse from remission, salvage therapy with platinum-containing drug regimens with or without surgery will cure most patients with resistant GTN.

INTRODUCTION

Breast cancer, a worldwide problem, remains the most common cancer diagnosis in women, affecting more than 1.2 million women diagnosed each year. Treatment paradigms require an understanding of the natural history of the disease, including the various patterns of metastases and recurrence, and both the prognostic and predictive factors that may influence both response to treatment and overall survival (OS). In addition, the complexities that govern medical and surgical decisions make the management of breast cancer far more complicated than that of other disease sites. This chapter will provide the essential information regarding breast cancer, with an emphasis on recent developments. It stresses an interdisciplinary view of disease management by providing the foundational aspects of breast disease and treatment.

EPIDEMIOLOGY

In 2012, an estimated 226,870 women and 2,190 men will be diagnosed with breast cancer in the United States (1). It is estimated that 1 in 8 women will be diagnosed with breast cancer in their lifetimes. Beginning in the late 1990s, a shift in the incidence of breast cancer in the United States was noted. The steady increase in breast cancer diagnoses seen in the 1950s started to decline in 1999 and continued to decline into 2003. The decline in the annual incidence between 2002 and 2003 was limited to women over 50 years of age. Whether the declining use of hormone replacement therapy following publication of the Women's Health Initiative study results, the utilization of mammographic screening, and earlier diagnosis of disease, or whether a combination of these factors, explains this trend continues to be an area of investigation. Mortality from breast cancer has been steadily declining since 1990, at a rate of 3.1% per year in women under 50 years of age and 2.1% per year in older women (1). Still, over 40,000 women will succumb to breast cancer this year, making it second only to lung cancer.

RISK FACTORS

Risk factors for breast cancer have been well characterized. Breast cancer is 100 times more frequent in women than in men. Factors associated with an increased exposure to estrogen have also been elucidated, including early menarche, late menopause, late age at first pregnancy, or nulliparity. The use of hormone replacement therapy has been confirmed as a risk factor, although mostly limited to the combined use of estrogen and progesterone, as demonstrated in the Women's Health Initiative (WHI) study (2). Analysis showed that the risk of breast cancer among women using estrogen and progesterone was increased by 24% compared to placebo. A separate arm of the WHI study randomized women with a prior hysterectomy to conjugated equine-estrogen (CEE) versus placebo, and in that study, the use of CEE was not associated with an increased risk of breast cancer (3). Unlike hormone replacement therapy, there is no evidence that oral contraceptive use (OCP) increases risk. A large population-based case-control study examining the risk of breast cancer among women who previously used or were currently using OCPs was conducted and included over 9,000 women 35 to 64 years of age (half of whom had breast cancer) (4). The reported relative risk was 1.0 (95% confidence interval [CI], 0.8–1.3) among women currently using OCPs and 0.9 (95% CI, 0.8–1.0) among prior users. In addition, neither race nor family history was associated with a greater risk of breast cancer among OCP users.

Apart from endocrine risk factors, sociodemographic risks have also been established. Breast cancer is an age-related phenomenon, with peak incidence after 40 years of age. Family history is also a strong epidemiologic risk factor. Clinical models can now be employed to predict the risk of breast cancer. Among those in common use are the Gail and Claus models (Table 28.1) (5,6). Although they have been widely used in the African-American population and other minority populations, they have not been validated sufficiently.

Beyond classification of risk based on family history (familial risk), the identification of genetic mutations that are passed in an autosomal dominant fashion (hereditary risk) has been

Table 28.1 Models for Estimating Risk for Breast Cancer

	Gail ^a	Claus ^b
Source	Breast Cancer Detection Demonstration Project (n = 284,780)	Cancer and Steroid Hormone Study (n = 9,418)
Personal Risk Factors	Age Age at menarche Prior breast biopsies Age at first live birth	Age
Family History	Number of <i>maternal</i> first-degree relatives with breast cancer	Number of relatives with breast cancer (beyond first-degree relatives) and ages of onset
Calculations	Absolute risk ^c at 5 years Lifetime risk up to 90 years old	Lifetime risk up to 80 years old
Limitations	Excludes paternal history Excludes ovarian cancer history Does not use pathological findings from breast biopsy Does not account for age of onset of breast cancer among family Not validated in other ethnic groups	Excludes other risk factors May underestimate risk in families with 3 or more family members with breast cancer

^bClaus EB, Risch N, Thompson WD. Autosomal dominant inheritance of early-onset breast cancer. Implications for risk prediction. *Cancer.* 1994;73(3):643–651.

^cRisk defined for invasive breast cancer only.

an important scientific finding. Among the most significant was the identification of mutations at *BRCA1*, localized to chromosome 17q21, and *BRCA2*, on chromosome 13q12–13, both of which confer a risk for breast cancer as high as 80% among carriers (7,8). A specific *BRCA1* mutation, 185delAG, has been identified in over 20% of Jewish women younger than 40 years of age at the time of breast cancer diagnosis. Other mutations known to carry an increased risk are those involving p53 in Li-Fraumeni syndrome (associated with other cancers, including sarcoma, leukemia, melanoma, gastrointestinal carcinomas, and brain tumors); *CHEK-2*, *PTEN* mutations associated with Cowden syndrome (associated with macrocephaly, intellectual disability and hamartomas with an increased incidence of endometrial cancer, benign and malignant thyroid disease, and noncancerous brain tumors); and *STK-11* mutations associated with Peutz-Jeghers syndrome (associated with hamartomatous polyps of the gastrointestinal tract, dark-colored spots on lips, mucous membranes and palms/soles, and an increased incidence of gastrointestinal, ovarian, and cervical malignancy).

Work evaluating the long-term effects of environmental factors has established prior radiation exposure as an additional risk factor. The therapeutic use of mantle-field radiation in women with Hodgkin's disease and the sequelae of the atomic bombing of Japan in World War II identified the heightened risks of breast cancer, particularly in young women (9,10).

Among modifiable risk factors, obesity, weight gain in later life, and the consumption of alcohol have been identified in

prospective observational studies (11). The association of environmentally found trace elements and breast cancer risk has also been evaluated, with unconvincing results in general.

An association has been made between breast cancer risk and breast findings. Among the best-described risk factors is the association between breast cancer and a history of biopsies for benign breast disease. In a study by Hartmann et al. the relative risk for breast cancer ranged from 1.27 for nonproliferative lesions, to 1.88 for proliferative lesions without atypia, to 4.24 in lesions with atypia, and this risk persisted for as long as 25 years after biopsy (12). A recent report from Worsham et al. evaluated the same risks in an intercity clinic and reported that African-American women with benign breast lesions faced similar risks in developing breast cancer (13). More recently, Boyd et al. reported on the association between risk and breast density (measured in percentage of the total breast). Using 1,112 matched case-control pairs, they determined the association between risk and reported that women with density of 75% or greater had a significantly increased risk of breast cancer (odds ratio, 4.7; 95% CI, 3.0–7.4), with younger women notably at greatest risk (14).

ANATOMY

The breast is a modified sweat gland composed of 2 components—the large ducts and the terminal duct-lobular unit (TDLU)—surrounded by adipose and fibrous tissue, lymphatics, nerves, and blood vessels. The surface of the breast is attached to the underlying fibrous tissue via Cooper's ligaments, and the mammary gland lies over the pectoralis major muscle extending vertically along the second to sixth ribs, and horizontally from the sternum to the anterior midaxillary line. The axillary tail comprises mammary tissue as well and extends laterally from the chest wall into the axilla. The large duct system of subsegmental, segmental, and lactiferous ducts converges and empties onto the nipple. The TDLU is the most distal part of this branching ductal system and is felt to be the site of origin of most pathologic entities of the breast, including fibrocystic changes, ductal hyperplasias, and the majority of carcinomas (15,16). It is connected to the subsegmental ducts and represents the secretory unit of the gland.

Mobility of the breast tissue over the chest wall is through the retromammary bursa that lies between the superficial and deep fascia. The lymphatic system of the breast is vast, comprising a network over the entire surface of the chest, neck, and abdomen, with increased density under the axilla. There are 3 main lymphatic pathways of the breast: (a) the axillary pathway, which drains the upper and lower halves of the breast into the lateral axillary nodal chain; (b) the transpectoral pathway, which drains into the supraclavicular nodes; and (c) the internal mammary pathway, draining the inner halves of the breast, into the nodes of the internal mammary chain.

NATURAL HISTORY OF BREAST CANCER

Breast cancer can occur with predictable features. For example, it is more likely to be diagnosed in the central or outer quadrants of the breast than in the inner regions (17). It has also been reported to be more commonly involving the left breast. One study of 2,139 cases of breast cancer in Iceland showed 13% more breast cancers occurred in the left breast versus the right (18).

Within the breast, cancer travels along ducts (intraductal carcinoma), and the process of invasion begins when the tumor

erodes through the basement membrane. Continued growth results as the tumor spreads along adjacent lobules, breast lymphatics, perineural tumors, and vascular spaces. When it involves the dermal lymphatics, the overlying dermis becomes edematous and red with the classic appearance of *peau d'orange*. Continued growth of the primary tumor can result in the involvement of the pectoralis and intercostal muscles, ribs, and the clavicle.

While less frequently encountered, locally advanced or metastatic disease at diagnosis still occurs in clinical practice. Tumor spread can occur locally by direct extension, lymphatically, or via intravascular means. Lymphatic spread of tumor from the breast travels to the locoregional nodes of the chest—the axillary, intramammary, and supraclavicular nodal basins—and increasing tumor size is a well-known predictor of nodal involvement. A medial or central lesion of the breast is more likely to metastasize to the internal mammary nodes than outer quadrant lesions, and this has been theorized to explain their worse prognosis compared to upper outer breast tumors (17). Vascular invasion can be observed, even with small tumors.

Metastatic disease from breast cancer can occur in any organ site. Lee reviewed the published autopsy series involving over 2,000 women who had died of breast cancer (19). The most commonly involved organs were the lungs, bones, nodes, and liver. The pleural space, adrenal glands, and brain represented the next most commonly involved sites. Bloom et al. compared a group of women with untreated breast cancer to a cohort of patients treated with radical or modified radical mastectomy, with or without irradiation, and reported an overall 10-year survival of 3.6% in the untreated cohort versus 34% in the treated group.

Theories on the spread of breast cancer have been used as a foundation for subsequent treatment and have evolved over time. Dr. William Halsted defined the notion that cancer arose from one location and travelled contiguously by lymphatics to reach local and distant locations. Hence, treatment with the *en bloc* resection of the breast and lymphatics was felt to present the best opportunity for cure. Still, it was clear that even with aggressive surgery and removal of the lymphatics from the breast, women still died of breast cancer. In a seminal paper by Valagussa et al., the OS was reported to be 60% among women with node-negative disease, 54% in those with up to 3 nodes positive, and 26% in those with more than 3 positive nodes. This showed that contiguous lymphatic spread alone could not explain survival outcomes (20).

The theory of breast cancer as a systemic disease was brought forward in 1980 by Dr. Bernard Fisher (21). Breast tumors were seen as a marker of this systemic syndrome, just as neuropathy would be a marker of advanced diabetes mellitus. Hence, nodal disease was not simply an extension of a primary breast cancer process, but rather a marker of disease already spread. This theory holds that achieving local control will not impact OS and argues for the use of systemic treatment in order to affect the best outcome. Recently, however, a meta-analysis on the use of adjuvant radiation by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) has called this theory into question. In that analysis, the use of adjuvant radiation not only improved local control but also reduced annual mortality by 13% after the second year of follow-up (22).

It is likely that breast tumors express variable degrees of malignancy. Hellman argued that “synthesis” between Halsted and Fisher's theories was required (23). Recognizing that tumor size is proportional to the risk of metastases, he argued that small and large tumors behave differently, and carried different prognoses. Small tumors were a manifestation of a locoregional process and therefore were curable with treatment. Larger tumors, on the other hand, comprised cells more likely to proliferate and be more malignant—features that made them more likely to metastasize. As such, these were likely to be associated with systemic disease. Defining cure as “that proportion of the
